3ds Max provides tools that give you control over the positioning and alignment of objects in 3D space. With these tools, you can do the following:

- Choose display units from the most common real-world measuring systems or define your own.
- Use the home grid as a construction plane, or use grid objects to position custom construction planes.
- Select different options to align objects with grids, points, and normals.
- Use 3D object snaps on a modeless dialog as you build and move geometry in your scene. Grid points and lines are among the many snap options.
- Use "helper objects" in your work. This category includes grid objects as well as objects used for positioning and measurement.

This section presents these brief topics designed to help you quickly start learning how to use the tools that make precision possible:

- **Using Grid Objects** (page 2–5)
- **Aligning Objects** (page 2–8)
- **Aligning Normals** (page 2–10)
- **Setting Standard Snaps** (page 2–11)
- **Setting Snap Options** (page 2–12)
- **Measure Distance Tool** (page 2–15)

### Tools for Precision

A set of interrelated tools in the program gives you precise control of the scale, placement, and movement of objects in your scene. These are especially important tools for those who build precise models in real-world units of measurement.

### Basic Tools

The tools for precision are grouped as follows:

- **Units**—Define different measurement systems. Besides the generic unit, you have your choice of feet and inches in both decimals and fractions. Metric units range from millimeters to kilometers. You can also define other units.

- **Grids**—Include the home grid and special grid objects. Both types of grid can act as construction
planes. The software constructs objects using the orientation and position of the active grid. While the home grid is fixed in world space, you can rotate grid objects and place them anywhere in a scene, and align them to other objects and surfaces. You can also give each grid object its own spacing, and display any grid as a dedicated viewport.

**Object alignment**—Matches an object with the position, orientation, or normal of another object, or to a point in space.

**Object snaps**—Ensure precise placement when creating and rearranging objects. Keyboard shortcuts let you change object snaps as you work. You can also set snaps to find grid lines and intersections. An angle snap sets the increment for rotation, and a percent snap sets the increment for scaling.

**Helpers**—Provide useful assistance, as the name implies. These are specialized tools in the same category as grid objects. A Tape object measures distances in current units, and a Protractor object measure angles. A Grid object defines a construction plane, and a Point object marks a particular spot in 3D space.

**How the Tools Work Together**
The tools themselves establish a general order of use and interaction, although you can always change settings as needed without following this sequence.

- Choose a measuring unit. The default is generic units, sufficient for many purposes.
- Set grid spacing (the size of the smallest square), based on the measuring unit. The home grid and grid objects can have their own spacing, separate from the grid spacing.
- Move and align grid objects to a useful orientation.
- Set or vary snap settings as needed in your work.
- Use other helper objects like Point and Tape as part of the precision process.

As you work, you can change your settings (including the measuring unit) without losing any precision.

**Helpers**

- Create panel > Helpers
- Create menu > Helpers

Helper objects play a supporting role, like stage hands or construction assistants.

Several categories of helpers are available from the drop-down list on the Create panel:

- **Standard helpers** (page 2–16)
- **Atmospheric Apparatus** (page 3–304)
- **Camera Match Helper** (page 2–1391)
- **Assembly Head Helper Object** (page 1–111)
- **Character Assembly** (page 1–102)
- **Luminaire Helper Object** (page 1–111)
- **Manipulator Helper Objects** (page 2–27)
- **Particle Flow** (Speed By Icon Operator (page 2–162) and Find Target Test (page 2–218))
- **VRML97 Helper Objects** (page 3–597)
- **reactor** (page 2–703)

Other helper objects might be available, depending on your configuration.

**Using Units**

Units are the key to connecting the three-dimensional world of 3ds Max with
the physical world. You define the units you want to use from the Units Setup dialog (page 3–848).

**Changing Display Units**

When you change display units, 3ds Max displays measurements in the new unit for your convenience. All dimensions are displayed in the new unit. Essentially, you’re using a new “measuring stick.” No object is changed in this process. As in the physical world, objects in the scene maintain their absolute size, regardless of how you measure them.

**Type-In Entry**

When you enter any dimension, 3ds Max always assumes the number you enter is expressed in the current units. You can also enter a series of numbers: 3ds Max then converts their sum into the current unit. Here are some examples that assume the current units are in centimeters:

- When you enter a dimension of 1’ (one US foot), it converts to 30.48cm.
- If you enter a series of numbers such as 14 286 175 (separated by spaces), the series is totaled to 475.0cm.
- If you enter 1’ 1 (one US foot and 1 centimeter), this is converted and summed into 31.48cm.

When you use US Standard as the display unit scale, you can select either feet or inches as the default for type-in entry. If you select feet and enter 12, the result is 12’ 0”. However, if you enter 1’ 2”, the software identifies the second digit as inches, producing 1’ 2” as the result.

In any unit system, you can enter fractional amounts. For example, assume you’re working in US Standard with feet as the default:

- If you enter 18/3, the result is 6’0”.
- If you enter 18/3”, the result is 0’6”.
- You can specify units in a different system, and they are converted on the fly. For example, if you enter 18/3cm, the result is 0’2.362”.

**Understanding the System Unit**

3ds Max keeps track of all measurements in its own internal system unit. No matter what kind of display units you use, measurements are stored in this absolute unit for storage and computation. The default system unit is defined as 1.000 inch. As long as the system unit is left at one inch, you can freely share models and change units on the fly with no effect on the underlying geometry. Except in rare circumstances, you never need to change this default scale. This means you can merge a model created with any standard unit into your scene at true scale.

You can change the system unit setting on the System Unit Setup dialog, available from the Units Setup dialog (page 3–848). Changing the system unit is recommended only if your scene has very small (less than one inch) or very large dimensions. See System Unit Setup Dialog (page 3–850) for more information.

If you do need to change the system unit, change it before you create or import geometry. Do not change the system unit in an existing scene.
Chapter 10: Precision and Drawing Aids

Using Grids

Grids are two-dimensional arrays of lines similar to graph paper, except that you can adjust the spacing and other features of the grid to the needs of your work.

Grids have these primary uses:

- As an aid in visualizing space, scale, and distance.
- As construction planes where you create and align objects in your scene.
- As a reference system for using the Snap feature to align objects.

Home Grid and Grid Objects

3ds Max provides two kinds of grids: the home grid and grid objects. In addition, it includes the AutoGrid feature, an automated way of creating grid objects.

Home grid—The home grid is defined by three planes along the world X, Y, and Z axes. Each of these axes passes through the world coordinate system’s origin point (0,0,0). The home grid is fixed; it cannot be moved or rotated.

- The home grid is visible by default when you start 3ds Max, but its display can be turned off.

- You can use any view of the home grid as a construction plane by drawing in the viewport in which the grid’s view appears.

See Viewing and Navigating 3D Space (page 1–21) for a complete introduction to the home grid.

Grid objects—A grid object is a helper object you can create whenever you need a local reference grid or construction plane somewhere other than the home grid.

- You can have any number of grid objects in your scene, but only one can be active at a time.
- When active, a grid object replaces the home grid in all viewports.
- Each grid object has its own set of XY, YZ, and ZX planes. You can freely move and rotate grid objects, placing them at any angle in space, or attach them to objects and surfaces.
- You can change a viewport to display a plan (top) view of any active grid object.
- Grid objects can be named and saved like other objects, or used once and deleted.

AutoGrid—This feature lets you create new objects and grid objects off the surfaces of other objects on the fly. See AutoGrid (page 2–7).

Using the Home Grid

The home grid provides ready-to-use construction planes, much like a leveled building site marked with stakes and strings. When you create an object in a viewport, the new object is placed on the home grid plane of that viewport.

To use the home grid effectively for construction, you often need to change the defaults to the job at hand, analogous to moving the stakes and strings to match your own site plan.
Changing Home Grid Settings

The home grid is a single system; its three planes use the same settings for grid spacing and major line divisions. You change these settings from a single panel of the Grid and Snap Settings dialog.

To access the Home Grid panel, do one of the following:

- Choose Customize menu > Grid And Snap Settings, then click the Home Grid tab.
- Right-click any snap button (page 2–35), then click the Home Grid tab.

Setting Grid Spacing

Grid spacing is the size, in current units, of the grid’s smallest square. The basic idea is to choose a grid spacing that corresponds to your unit of measurement, then choose a larger spacing for multiple units.

For example, if you have units set to centimeters, you might make one grid space equal to 1.000 (one unit, or one centimeter in this case).

Setting Major Grid Divisions

The home grid displays heavier or "major" lines to mark groups of grid squares. You can use these to represent larger units of measurement.

For example, if you use a grid spacing of one centimeter, you might use a value of 10 so the major grid divisions represent one decimeter.

Setting Color and Intensity

To improve grid visibility, you can change the intensity or color of the home grid. Choose Customize menu > Customize User Interface > Colors panel (page 3–799).

Using Grid Objects

Grid objects are 2D parametric objects, with adjustments for overall size and grid spacing. You can use as many grid objects as you like, each serving as a custom construction plane with its own grid settings.

Grid objects let you bypass the home grid and work on separately defined grids to create and position objects. You can use as many grid objects as you like, each serving as a custom construction plane with its own grid settings.

Using Grid Objects

Above: Inactive grid object in a scene
Below: Activated grid object
To activate a grid object:
1. Create a grid object.
2. Choose Views > Grids > Activate Grid Object.

To deactivate a grid object, do one of the following:
- Select and activate another grid object.
- Choose Views > Grids > Activate Home Grid.
- Delete the grid object.

Creating and Modifying Grid Objects

You find Grid objects in the Create panel > Helpers category.

When creating an object, you can also create a temporary "AutoGrid" grid object that’s tangent to an existing object surface at the point you click. To do this, turn on the AutoGrid (page 2–7) check box in the Object Type rollout. You can save this grid by holding the Alt key before you click.

Grid objects are named when you create them and are saved with the scene. You can delete them at any time.

Like other objects created in 3ds Max, standard grid objects are placed on the grid of the current viewport. By default, this is a plane of the home grid, but can also be another activated grid object.

For more information on grid object settings, see Grid (page 2–20).

Setting the Display Plane

You can adjust the visible plane of a selected or activated grid object on the Modify panel.

To set the display plane:
1. Open the Modify panel to display the Parameters rollout for the selected grid.
2. In the Display group, choose any of the three planes: XY, YZ, or ZX.

The grid rotates in world space to display the corresponding plane, always based on the grid’s local axis.

You can move or rotate a grid, either before or after setting its display plane.

Setting Grid Views

You can set the view in any viewport to an orthographic view as well as the display view.

To set grid view:
1. Activate the grid object.
2. Right-click a viewport label and choose Views > Grid to display a menu of possible views.
3. Choose Front, Back, Top, Bottom, Right, Left, or Display Planes. Display Planes corresponds to the current setting on the Parameters rollout (XY, YZ, or ZX).

The viewport now shows this view of the grid.

You can set different viewports to different views of the grid. Objects are always created on a view’s orthographic grid, even if you rotate the angle of view. In other words, you can set up a convenient view and still construct on the chosen plane.

Deactivating Grid Objects

You can deactivate a grid object in any of the following ways:
- Select and activate another grid object.
Choose Views > Grids > Activate Home Grid.

- Delete the grid object.

When you deactivate a grid object, any viewports based on that grid switch to the corresponding orthographic view. For example, a Grid (Front) viewport becomes a Front viewport. A Grid (Display Planes) viewport always switches to Top view, regardless of the currently displayed plane.

AutoGrid

Create panel > Any object category > Object Type rollout
Extras toolbar > AutoGrid

AutoGrid used to position the second block on top of the first

AutoGrid lets you automatically create, merge, or import objects on the surface of other objects by generating and activating a temporary construction plane based on normals of the face that you click. This serves as a more efficient way of stacking objects as you create them, rather than building objects and then aligning them as a separate step.

You can use objects within an XRef scene as reference when AutoGrid is on.

Note: If the Smooth check box is turned on in the Parameters rollout of a parametric object, the construction plane is placed tangent to the face of the surface implied by any smoothing present on the surface, not the actual face of the surface.

Procedure

Example: To create a box aligned to another object using a temporary construction grid:

1. Create or load a scene containing an object to which you want to align a new box.
2. On the Create panel > Standard Primitives > Object Type rollout, click Box.

3. Turn on AutoGrid.

4. Move your cursor over the object to which you want to orient the box you are about to create. The cursor includes an X,Y,Z tripod to help you orient the position of the new object. As you move over the object, the cursor aligns the Z axis to the surface normal.

5. When the orientation is as you want it, click and use the standard drag-release-move-click method to create the box. The box will be created on the designated surface. When you click, a temporary, automatic grid is created, and the newly created object is aligned to that grid.

Interface

Object Type rollout

AutoGrid—AutoGrid is available only after you select an object button (such as Box). When you turn AutoGrid on, the cursor includes an axis tripod to help you orient the grid. Before clicking and as you position the cursor over a visible mesh object, the cursor jumps to the nearest point on that surface. The tripod’s X and Y axes form a plane tangent to the object surface (forming an implied construction grid), and the Z axis is perpendicular to the plane.

After creating the object, 3ds Max places it on the temporary construction grid. When creating an object, if the cursor isn’t over another object, 3ds Max places the object on the current active grid.

Tip: When you create an object that requires multiple clicks, AutoGrid applies only to the first click. So, for instance, if you want to create a Line spline (page 1–270) that snaps to the faces of a sphere, turn on Snaps (page 2–35) (press the S key), and then open the Grid And Snap Settings dialog (page 2–41) and turn on Face.

Note: To make the grid permanent, hold down the Alt key before you click. The grid becomes active and 3ds Max turns AutoGrid off.

Aligning Objects

You can align a selection consisting of one or more objects, called the source, with a target object. There are many uses for this feature. For precision, an important use is grid alignment. You can create a new grid object and align it to an existing object, either manually after creation or automatically during creation using the AutoGrid (page 2–7) feature. Conversely, you can move an object onto a grid anywhere in your scene.
Aligning Objects

Source and Target Objects
Alignment involves two entities: one is the source object or selection set, where the process begins; the other is the target object, where the selection process ends.

Source object—Object or objects you want to move into alignment with another object. You select one or more source objects to begin the alignment process.

Target object—Object used to define the alignment. You select the target object during the alignment process. It cannot be selected beforehand.

After selecting the source, choose Tools menu > Align or click the Align button on the Main toolbar, and then select the target object.

Next, the Align dialog appears. For discussion of the Align options, see Align (page 1–462).

Setting a Coordinate System
The effects of alignment depend on the current reference coordinate system, such as View, World, or Local. You should decide which system you want to use before beginning alignment.

Reference Coordinate System—Determines the axes used for positional alignment and the size of the bounding box for maximum and minimum positions.

To align objects using active grid axes:
- Choose Grid as the reference coordinate system from the list on the toolbar.

To align two objects using their own axes:
- Choose Local as the reference coordinate system. Alignment is then strictly between the two objects. Object bounding boxes determine maximum and minimum positions.

As a reminder to you during the alignment process, the current reference coordinate system appears in parentheses following the Align Position label in the Align Selection dialog.

Basics of Aligning Objects
Alignment controls are on a single dialog. As you make a setting, the object being aligned moves immediately to the new position. This lets you experiment with alignment until you get what you want. Settings can be made in any order.

You can also work step-by-step, by applying position choices, for example, before deciding on final orientation. You can cancel at any time, returning the scene to its original state. You can also undo any alignment and start over.
Aligning Multiple Objects

Aligning multiple objects to the arrow object (each photo is adjusted in a different correction)

When you select multiple objects for alignment, the same settings apply to all of them. However, the effect on each source object can be different. In practice, you’re aligning separate objects at the same time with the same settings.

To align a collection of objects as a single unit, select the objects and group (page 1–96) them. The alignment now takes place relative to the pivot and bounding box of the entire group.

Sub-Object Alignment

You can use Align with any selection that can be transformed. The tripod axis becomes the source for alignment. You do this by accessing the sub-object level of the object before clicking Align.

Aligning Normals

Normal on the front of the bolt is aligned with the normal of a face on the assembly.

3ds Max lets you align the normals between any two objects. In the case of mesh objects, the alignment is between individual faces, because each face has its own normal. See Normal Align (page 1–465).

Basics of Aligning Normals

Before you begin, select a view that lets you see both objects you want to align. If necessary, you can navigate the view after selecting the first normal. To see face normals clearly, work in a wireframe viewport.

For details on the procedure and dialog settings, see Normal Align (page 1–465).

Other Align Options

The Align flyout on the main toolbar has other buttons that provide specialized alignments.

Align Camera—Orients a camera viewport to a selected face normal, with the normal in the center of the viewport and on the axis of the camera. See Align Camera (page 1–468).
Setting Standard Snaps

Align to View—Orients a local axis of an object or sub-object selection with the current viewport. Options on the dialog are interactive, as they are on the Normal Align dialog. See Align to View (page 1–468).

Place Highlight—Orients a face normal to a light. See Place Highlight (page 1–467) and Lighting in 3ds Max (page 2–1279).

Grid And Snap Settings Dialog and Snaps Toolbar

The most commonly used grid and object snaps appear on the Grid and Snap Settings dialog (page 2–41). This is the general sequence for using these snaps:

1. Turn on snapping by clicking the Snaps Toggle button on the main toolbar, and then right-click this button to display the Grid And Snap Settings dialog.

   Two sets of snap types are available: Standard (the default) and NURBS. Both are discussed in Snap Settings (page 2–41).

   You can also make commonly used snap settings on the Snaps toolbar (page 2–42).

2. By default, only the Grid Points snap type is active. Turn on other snap types to activate them. When you create or move objects, these snaps are now in effect anywhere in 3D space, and unaffected by the current transform coordinate system.

   As you move the cursor, each snap type is marked by a distinctive icon shown on the Snap panel. The current icon indicates the type and position of the next snap.

   Grid points and grid lines are secondary to the other snap types. For example, if both Grid Point and Vertex are active, the software snaps to a vertex in preference to an equally close grid point.

3. Turn snaps on and off as needed; the easiest way is by pressing the S key.

For more information on snaps, see 2D Snap, 2.5D Snap, 3D Snap (page 2–35) and Snap Settings (page 2–41).
Snap Override

Snap Override bypasses currently selected snaps. You use a keyboard-mouse combination or a keyboard shortcut to define a new snap for the next click. You can override on the fly, one snap at a time.

For example, while creating a spline between grid points, you might need to snap to a vertex or midpoint of an object. This is the general procedure:

1. As you use preset snaps to create or move an object, hold down Shift and right-click. This pops up a three-quadrant right-click menu, which you can use to override the current snap setting(s).

   Note: You can begin the creation or transformation process before accessing the override menu. This typically means that you'll be holding down the left button as you Shift+right-click.

2. From the Snap Override quadrant, choose the snap type you want to use. The cursor switches to this type.

3. Make the snap. After the snap, currently set snaps are back in effect.

In addition, the Snap Override quadrant lets you reuse the last override you used (listed by name), and gives you an option for None. None turns off snapping entirely on the next click. The Snap quad menu also contains an Options quadrant, with toggles for snapping within current transform constraints (default=off) and snapping to frozen objects (default=off).

Setting Snap Options

You can access a number of snap features from the Options tab of the Grid and Snap Settings dialog. Right-click any of the snap buttons on the main toolbar to display the Grid And Snap Settings dialog or choose Customize menu > Grid And Snap Settings, then click the Options tab.

See also
Snap Options (page 2–46)

Display and General Settings

Marker settings—Determine the color and size of the snap cursor. To prevent the snap cursor from appearing, turn off Display.

Snap Radius settings—Determines how close the cursor needs to approach a snap point before the snap preview or actual snap takes place. These are global settings, affecting all snap interactions, and are measured in terms of the pixels in a "search region" around the active point of the cursor.

Snap to Frozen Objects—Normally, if an object is frozen you can't snap to it; this option lets you snap to frozen objects.

Settings for Angle and Percent Snap

The following Options settings are for two snap buttons that operate independently of standard snaps.
Angle (deg)—A global setting, in degrees, that determines the angle of rotation for a number of features in the program, including the standard Rotate transform. As you rotate an object (or group of objects), the object moves around a given axis in the increment you set. Angle snap also affects the following:

- Pan/Orbit camera controls
- FOV and Roll camera settings
- Hotspot and Falloff light angles

For more information, see Angle Snap (page 2–37).

Percent—Sets a percentage increment during a scaling operation.

For more information, see Percent Snap (page 2–38).

Rotating and Scaling with Snaps

The effect of rotating and scaling with snaps depends on whether Auto Key (page 3–717) is on or off:

- With Auto Key on, snap toggles are disabled, while Angle and Percent snaps remain active. Rotation and scaling occur around the pivot point of the object.
- With Auto Key off, rotations and scales occur around the snap point. For example, using Vertex snap, you can rotate a box about any of its corners.

Translation Options

By default, the Use Axis Constraints (page 1–437) option is off. The current setting on the Axis Constraints toolbar (XY, for example) has no effect. Turning on this option lets you use snaps in conjunction with axis constraints.

The Translation group also lets you toggle display of a rubber band line between the start and end points during a snap operation.

Settings for Spinner Snap

You set the spinner snap on the General panel (page 3–815) of the Preferences dialog. Right-click the Spinner Snap button on the main toolbar to display this panel.

Spinner snap—Sets a numerical increment for spinner fields. If you’re using generic units of 1 inch, a setting of 12 would let you resize objects by one foot with every click, or add 12 segments to a sphere.

The same setting applies to all spinner fields. Since spinner snap is a toggle, you can easily turn it on when needed and use the default at other times. Spinner snap has no effect on dragging a spinner, only on single clicks.

For more information, see Spinner Snap (page 2–38).

Measuring Distances

3ds Max provides several options for measuring various aspects of your scene. The tape, protractor and compass helpers measure distance, angles and direction respectively. The Measure utility has a float to display various measurements of any selected object.

You can quickly measure the distance between two points with the Measure Distance tool (page 2–15).

Helper Objects for Measurement

Tape Helper

You can create a Tape helper (page 2–24) by dragging between any two points in 3D space, much like using a physical tape measure. You then read the length on the Parameters rollout.

If you turn on Specify Length, the length field lets you enter a value in current units. This is like
locking a tape measure to a set length. You can position the tape object and snap to its ends.

The pyramid icon is the tape helper object; the cube is the helper object’s target.

• To display length and angle settings, select only the tape helper object (the pyramid icon).
• To move the entire tape including its target (the cube icon), select the connecting line.

Two sets of World Space Angles give you current readouts to the three world axes (X, Y, Z) and the three world planes (XY, YZ, ZX).

Tip: When measuring with precision, it is helpful to use snaps to force the ends of the tape object to exact locations. If there are no specific points to snap to, you can use dummy or point helpers to set points.

To measure with a tape helper using snaps:

1. Locate points in the scene to which you can snap to accurately make a measurement. If no points like this exist, create point objects (page 2–23) at measurement extremes.
2. Choose 3D from the Snap Toggle flyout.
3. Right-click the Snap Toggle button to display the Grid and Snap Settings dialog. On the Snaps tab, set the snap type to the type you will use for measurement. For example, if you are going to use point objects for measurement, check the Pivot option so you can snap to the point objects’ pivot points. Close the dialog.
4. On the Create panel, click the Helpers button, then click Tape. Move the cursor over the first measurement point until the snap cursor appears, then click and drag to the other measurement point.
5. Read the length of the tape on the Parameters rollout.

Protractor

The Protractor helper (page 2–26) measures the angle between pivot points of two objects and the protractor object.

As with the tape helper, point objects and snap tools can be used to aid in precise measurement of angles.

To measure an angle with a protractor:

1. On the Create panel, click the Helpers button, then click Protractor. Click in a viewport to place the protractor object.
2. On the Parameters rollout, click Pick Object 1 and select an object in your scene. The name of the selected object appears above the pick button. A line connects the protractor to the center of the object.
3. Click Pick Object 2 and pick a second object. The angle between the protractor and the two objects appears on the rollout.
4. To move either object while watching the Angle readout, turn on the Pin Stack button in the Modifier Stack rollout. This locks the stack to the Protractor’s Parameters rollout.

Compass

The Compass helper (page 2–27) establishes an orientation for your scene. You create this object with a single click and drag to define the radius, usually in a Perspective or Top view. On its parameters rollout, you can adjust the apparent
radius of the compass rose. Like all helper objects, this object is for reference only and does not render.

**Measure Utility**

The *Measure Utility (page 2–52)* provides measurements of a selected object or shape.

**To use the Measure utility:**

1. On the Utilities panel, click Measure to display the Measure rollout.
2. Select any shape or object and read out the measurements. If you select multiple objects, the sum of the measurements is displayed.
3. Click New Floater to display a modeless Measure dialog with all the same information.
4. Use the Measure dialog to display the length of a spline, like a line or circle, as you create it.

**Measure Distance Tool**

The Measure Distance tool quickly calculates the distance between two points.

**To measure the distance between two points:**

1. Choose Tools menu > Measure Distance.
2. Click in the viewport where you want to start measuring.
3. Click again in the viewport where you want to measure to.

A distance is returned in the Mini Listener. Additional information, detailing the distance along the X, Y, and Z coordinates is displayed as well.

**Select And Manipulate**

The Select And Manipulate tool lets you edit the parameters of certain objects, modifiers, and controllers by dragging "manipulators" in viewports.

**Procedure**

**To measure the distance between two points:**

1. Choose Tools menu > Measure Distance.
2. Click in the viewport where you want to start measuring from.
3. Click again in the viewport where you want to measure to.

A distance is returned in the status bar. Additional information, detailing the distance along the X, Y, and Z coordinates is displayed as well.
Cone Angle Manipulator (page 2–27)
Plane Angle Manipulator (page 2–29)
Slider Manipulator (page 2–31)

These features have manipulators built in, which you can use to change parameters on these objects:
IK Solver Properties Rollout (HI Solver) (page 2–456)
Reaction Controllers (page 2–358)
Target Spotlight (page 2–1289)
Target Direct Light (page 2–1292)
mr Area Spotlight (page 2–1299)
Free Spotlight (page 2–1290)

Spotlight Parameters (page 2–1338)
UVW Map Modifier (page 1–922)
Primitives (page 1–169) with a Radius parameter have a built-in manipulator for the radius.

Standard Helper Objects

Create panel > Helpers > Standard > Object Type rollout

Create menu > Helpers

<table>
<thead>
<tr>
<th>Object Type</th>

<tbody>
<tr>
<td>Dummy</td>
</tr>
<tr>
<td>Delegate</td>
</tr>
<tr>
<td>Grid</td>
</tr>
<tr>
<td>Tape</td>
</tr>
<tr>
<td>Compass</td>
</tr>
</tbody>
</table>

The standard set of helper objects includes the following:

- Dummy Helper (page 2–16)
- Crowd Helper (page 2–1187)
- Delegate Helper
- Expose Transform Helper (page 2–17)
- Grid Helper (page 2–20)
- Point Helper (page 2–23)
- Tape Helper (page 2–24)
- Protractor Helper (page 2–26)
- Compass Helper (page 2–27)

reactor Helpers (page 2–715)

Dummy Helper

Create panel > Helpers > Standard > Object Type rollout > Dummy

Create menu > Helpers > Dummy

A Dummy helper object is a wireframe cube with a pivot point at its geometric center. It has a name but no parameters, you can’t modify it, and it doesn’t render. Its only real feature is its pivot, used as a center for transforms. The wireframe acts as a reference for transform effects.

The dummy object is used primarily in hierarchical linkages. For example, you can use a dummy object as a center of rotation by linking a number
of different objects to it. When you rotate the dummy, all of its linked children rotate with it. A dummy is often used this way to animate linked motion.

Another common usage of a dummy object is in the animation of target cameras. You can create a dummy and position a target camera within the dummy object. Then you can link both the camera and its target to the dummy, and animate the dummy with a path constraint. The target camera will follow the dummy along the path.

Dummy objects are always created as cubes. You can change the proportions of dummies by using non-uniform scaling, but avoid this on dummies that are within a hierarchical linkage; this can introduce unexpected results.

Procedure

To create a dummy object:

- Click Dummy and drag a cube to any convenient size.

Interface

Dummy objects don’t have any parameter rollouts or settings.

Expose Transform Helper

Create menu > Helpers > Standard > ExposeTm

The Expose Transform helper exposes values of non-keyed objects for use in expressions and scripts. This lets riggers and animators access a select set of transforms for an object, and between an object and its parent, such as a bone in an IK chain. For example, using the Expose Transform helper, you could write a script or use parameter wiring that tests the angle of an character’s arm bone that’s controlled by IK (thus, has no keys), and once it exceeds a specific value, rotate the corresponding clavicle bone to deform the shoulder area.

In the viewports, the Expose Transform helper object looks just like a Point helper (page 2–23).

Procedure

To use the Transform helper:

1. Click ExposeTm and choose the appearance characteristics from the Display rollout.

2. Adjust the size of the helper object by using the Size spinner on the Display rollout.
   Default=20.0

3. Click anywhere in your scene to add the helper object.
   The helper object’s position has no bearing on its functionality.

4. On the Modify panel > Parameters rollout, click the Expose Node button (default label: None) and select the object whose transform values you want to expose.
   The object’s name appears on the button, and its transform values appear in the fields on the Expose Values rollout.

5. Optionally, turn off Parent and choose a Local Reference Node object.
   This option is used by the Local Euler Angles, Distance To Reference, and Angle parameters. If the object has no parent and you don’t specify a Local Reference Node object, these fields use the world center (0,0,0) as the reference node.

6. To use a transform value in a script or expression, first click the M button next to the parameter value.
   This copies the transform name, using MAXScript notation, to the copy buffer.

7. Paste the contents of the buffer to your script or expression.
A sample result of this is 
"$Expose\text{Transform01.localPositionX}". 
3ds Max interprets this as the local position, on 
the X axis, of the Expose Node object.

### Interface

**Parameters rollout**

These settings let you specify the exposed node, 
a reference object other than the parent, and 
rotation and timing parameters.

**Expose Node**—The object from which the values 
are generated. Click the button, and then select 
the object. Thereafter, the object name appears 
on the button.

**Local Reference Node**—The object whose 
relationship with the Expose Node object is used 
to generate local data for rotation, distance, and 
angle. Click the button, and then select the object. 
Available only when Parent is off.

By default, this is the parent object, but you can 
turn off Parent and then specify a different object.

**Parent**—When on, the Local Reference Node is set 
automatically to the parent of the Expose Node. 
When off, you can pick an object to refer to for 
local data. Default=on.

This is used by the Local Euler Angles, Distance To 
Reference, and Angle parameters. If the object has 
no parent and you don’t specify a Local Reference 
Node object, these fields use the world center 
(0,0,0) as the reference node.

**Rotation Order**—These three settings determine 
the order in which the Expose Transform helper 
will look for an Euler rotation.

This parameter corrects for anomalies that can 
be introduced when a local rotation value is 
generated in relation to other rotation values. For 
example, when Z Order is set to XYZ, the Z value 
is generated in reference to X and then Y. Or when 
X Order is set to ZXY, the Z value is generated 
directly in reference to the parent, regardless of X 
and Y rotations.

**Strip NU Scale**—When on, removes any 
non-uniform scaling that could influence the 
rotation data. It does not strip non-uniform 
scaling from the object; only from the values 
generated.

**Use Time Offset**—When on, lets you specify a 
frame other than the current one from which 
to gather data. The Offset value is added to the 
current frame to derive the frame from which data 
is gathered.

For example, if the current frame is 20 and you 
wish to gather data from frame 15, turn on Use 
Time Offset and set Offset to -5.
Display rollout

Let's you specify how the helper object appears in the viewports. By default, the display type is set to Cross only, and Size is set to 20.0. You can activate multiple display settings if you like.

Center Marker—Displays a small X marker at the center of the helper object.

Axis Tripod—Displays a tripod axis indicating the position and orientation of the helper object.

Cross—Displays an axis-aligned cross.

Box—Displays a small axis-aligned box at the center of the helper object.

Size—Sets the size for the helper object. Use this setting to minimize the helper object, or increase its size to aid in locating it. Default=20.0.

Constant Screen Size—Keeps the size of the helper object constant, regardless of how much you zoom in or out.

Draw On Top—Displays the helper object on top (or in front) of all other objects in the scene.

Exposed Values rollout

This rollout provides readouts of values for all transform values of the Expose Node object. Each value has a button labeled “M” next to it; click this...
button to copy the MAXScript associated with the value to the clipboard, which you can then paste into a script.

**Display Exposed Values**—When on, transform values for the Expose Node object appear on this rollout, and update as the values change. When off, values don’t appear, but the M buttons still function normally.

**Local Euler Angles**—Rotation values with respect to the parent or Local Reference Node object.

**World Euler Angles**—Rotation values in the world coordinate system.

**Local Position**—Position values with respect to the Expose Node object’s local coordinate system.

**World Position**—Position values in the world coordinate system.

**Bounding Box**—The maximum dimensions of the object.

**Distance to Reference**—The distance between the Expose Node object and its parent or the designated Local Reference Node object. If neither exists, this shows the distance to the world center (0,0,0).

**Angle**—The angle between the Expose Node object and its parent or the designated Local Reference Node object.

---

**Grid Helper**

- **Create panel > Helpers > Standard > Object Type rollout**
  - Grid
- **Create menu > Helpers > Grid**

The grid, also called User Grid or Custom Grid, is a 2D parametric object with adjustments for overall size and grid spacing. You can move and orient user grids anywhere in world space.

You can create any number of grid objects in your scene. You name them when you create them and save them with the scene. You can delete them at any time.

Like other objects you create in the software, grid objects are placed on the grid of the current viewport. By default, this is a plane of the home grid, but it can also be another activated grid object.

Note: You can use AutoGrid (page 2–7) to create a temporary or permanent user grid off the surface of any object.

---

**Using the Grid Object**

You can use the grid object as a construction plane on all three orthographic planes in both directions. Here’s how it works:

In the Parameters rollout of each grid object is a Display group with three options: XY Plane, YZ Plane, and ZX Plane. These determine which of the three planes of the grid object is displayed in the viewport.

When you activate a grid object, the displayed plane is the construction plane for all viewports. When you create a grid viewport, you can choose from one of six orthographic views (Front, Top, Left, and so on), or you can choose a special Display Planes grid viewport. (When you press the `G` key to create a grid viewport, the Display Planes type becomes the default.) The Display Planes type of grid viewport always displays the plane chosen by the three option buttons under Display. Thus, as you switch between XY Plane, YZ Plane, and ZX Plane, the view through the grid viewport switches accordingly, and objects created in that viewport are created on the displayed plane.

When you right-click a viewport label (or go to the Layout tab of the Viewport Configuration dialog), you can choose six additional types of grid viewports, based on the six orthographic views.
These are available by a cascading Grid menu that provides Left, Right, Front, Back, Top, Bottom, and Display Planes. Each of the orthographic directions is local to the grid object, regardless of its orientation in the scene.

When you choose a specific orthographic grid viewport (as opposed to the Display Planes viewport), the construction of objects in that viewport is on the plane specified in the viewport title regardless of the displayed plane of the grid object.

You can create more than one viewport based on the same grid object, with each using a different plane. For example, you can have a Grid (Front) viewport and a Grid (Top) viewport, as well as a Grid (Display Planes) viewport.

When you deactivate a grid object, its remaining viewports show the assigned orthographic view. Thus, a Grid (Front) viewport becomes a Front viewport, for example. A Grid (Display Planes) viewport always reverts to a Top view, regardless of the currently displayed plane.

Scaling Not Advised

As a rule, don’t use scaling to resize a grid object. Scaling enlarges or reduces the apparent size of the grid object but has no effect on grid spacing. A sphere 20 units in radius created on a grid object appears smaller than another 20-unit sphere created on a scaled-up version of the same grid.

If you want to change the actual size of the grid object, select it and go to the Modify panel > Parameters rollout > Grid Size group, and change the Length and Width settings.

Locating Grid Tools

Grid tools are spread throughout the 3ds Max interface.
- In the Views menu, under Grids, are the commands to activate home and user grids.

The same tools are available with a right-click anywhere in the viewport when a grid helper is selected.
- Choose Customize menu > Grid and Snap Settings to display the Grid and Snap Settings dialog (page 2–41). Two tabs are devoted to Grid tools, one for home, another for user grids. You can change parameters of any active grid using the Modify panel.

See also

Viewing Grid Objects (page 2–6)

Procedures

To create a grid object:

1. Click Create panel > Helpers > Standard > Object Type rollout > Grid.

   A Parameters rollout appears on the Create panel.

2. In a viewport, drag a rectangle and release the mouse button. This creates and selects a grid object, which appears in white wireframe, divided into four quadrants with coordinate axes at the center.

   While the newly created grid object is still selected, you can change its settings on the Parameters rollout.

   You can also create a grid object during object creation. Turn on AutoGrid, then press \[Alt\] during object creation. A grid is created at the same time as the object and remains displayed and active. See AutoGrid (page 2–7) for more information.

To activate a grid object:

A grid object requires activation before use. Standard selection doesn’t activate it unless you turn on the option to do so (see User Grids (page 2–51)).
Only one grid can be active for construction at a time, whether it’s the home grid or a grid object. Activating a user grid “deactivates” the home grid. Activating a grid object enables options to reactivate the home grid on the Views menu > Grids submenu and the Quad menu.

If you have more than one grid object in your scene, you have to activate each one separately. Select the grid object you want to make active and follow the same procedure. Activating another grid object deactivates the current one.

1. Select a grid object.
2. Do one of the following:
   • From the Views menu, choose Grids > Activate Grid Object.
   • Right-click the selected grid object and choose Activate Grid from the quad menu.

   The grid object changes to show its internal grid structure. Except for its main axes, the home grid disappears in all viewports.

To return to the home grid, do one of the following:
   • From the Views menu, choose Grids > Activate Home Grid.
   • Right-click the selected grid object and choose Activate Home Grid from the quad menu.

   This deactivates the grid object and returns the home grid in all views.

   If you delete an activated grid object, the home grid also reactivates.

   You can assign a keyboard shortcut to Activate Home Grid in the Keyboard panel (page 3–793) of the Customize User Interface dialog. This is useful if you need to move back and forth between different grids.

To use a grid object as construction plane:

When activated, a grid object replaces the home grid as the frame of reference for creating objects.

An activated grid object creates a true plane in 3D space. No matter how small an activated grid object appears on screen, its XY plane is effectively infinite, just as if it were the XY plane of the home grid.

1. Activate the grid object.
2. Create any category of object.

   3ds Max creates the object directly on the plane of the grid object, with the object’s Z axis perpendicular to the plane.

See Align (page 1–462) for details on aligning objects and grids.

Like other objects in the software, you can move and rotate grid objects freely using standard transformation methods. These transforms, along with alignment, are essential in positioning a construction plane in 3D space.

To nudge a grid object up or down:

1. Activate the grid object.
2. Press the + or − keys on the numeric keypad to move the grid object up or down.

   The Grid Nudge Distance is controlled in the Viewports panel (page 3–821) of the Preferences dialog.

</tbody>
</table>

Grid Size group
Sets the overall size of the grid object. This size determines the extents of a viewport set to the grid object. It doesn’t affect the useful limits of the grid, which extend infinitely.

Length/Width—Specifies the length and width of the grid.

Grid Spacing group
Grid—Specifies the size of the smallest square in the visible grid. This setting appears on the status line when the grid is activated.

Note: You can set Grid Spacing when a grid is selected, but you won’t see the grid spacing until the grid is activated.

Active Color group
Determines the color used to draw the grid in viewports when it’s not selected.

Gray—The active grid object is two shades of gray.

Object Color—The main grid lines use the assigned object color, while the secondary lines use a lighter intensity.

Home Color—The grid object uses the home grid color assigned via the Customize User Interface dialog (page 3–792).

Home Intensity—The grid object uses the grid intensity settings assigned to the home grid in the Customize User Interface dialog (page 3–792).

Display group
XY Plane, YZ Plane, ZX Plane—Determines which of the three planes of the grid object are displayed in the viewport.

Point Helper
Create menu > Helpers > Point

Point provides a specific location in 3D space that can be used as a reference or by other program functions.

Procedure
To create a point in space:
1. Click Point and check the type of display from the Parameters rollout.
2. Adjust the size of the point object by using the Size spinner in the Parameters rollout. Default=20.0
3. Left-click and drag anywhere in your scene.

The point follows the cursor until you release the mouse button, indicating the current location of the point object.
4. Move the cursor to where you want the point object and release the mouse button.

The point object appears using the display setting you chose.

You can move and rotate the point as needed using standard transformation methods.

<tr>
<td>- Constant Screen Size</td>
</tr>
<tr>
<td>- Draw On Top</td>
</tr>
</tbody>
</table>

**Center Marker**—Displays a small X marker at the center of the point object.

**Axis Tripod**—Displays a tripod axis indicating the position and orientation of the point object. The axis remains visible when the point object is no longer selected.

**Cross**—Displays an axis-aligned cross.

**Box**—Displays a small axis-aligned box at the center of the point object.

**Size**—Sets the size for the point object. Use this to minimize the point object, or increase its size to aid in locating it. Default=20.

**Constant Screen Size**—Keeps the size of the point object constant, regardless of how much you zoom in or out.

**Draw On Top**—Displays the point object on top of all other objects in the scene.

---

**Note:** You can also choose to activate multiple display settings.

---

**Tape Helper**

Create menu > Helpers > Tape Measure

![Using a tape helper to measure the distance from floor to window frame.](image)

Tape provides an on-screen "tape measure" for determining and setting distances. The tape is composed of two named objects, in the same way targeted lights and cameras are. By default, these are named Tape## and Tape##.Target. The tape and target icons are connected by a line representing the current distance between them.

You can drag a length (the default), or enter a specific length by turning on Specify Length. You can snap or align either end of the tape or link to objects in your scene. Deleting either end deletes the tape.

**Note:** When you add a Tape helper object, the software automatically assigns a Look At controller (page 2–344) to it, with the tape’s target object assigned as the Look At target. You can use the controller settings on the Motion panel to assign any other object in the scene as the Look At target.
Selection
You can select a tape-measure object from either end, or from the middle. When you click the connecting line, both ends of the tape object become selected so you can move them as one. Note that the same is true of target cameras and lights.

Note: Line selection is available only when clicking with the mouse. Region selection doesn’t work for this.

Tip: The Length readout of the tape object is displayed in the Modify panel only when you select the tape end of the object (as opposed to the target or link line). You can lock the Length display by activating the Pin Stack button while the tape end is selected, and then proceed to adjust any part of the tape object or any other object in your scene.

See also
Measure Distance Tool (page 2–15)

Procedures
To measure a distance:
1. Click Tape and drag from one point to create the tape, and then drag to a second point and release the mouse button to create the target.

   The distance between tape and target appears in the Length field. The number in the Length field is gray to indicate that this is a read-only measurement.

   Note: To snap the tape ends to object vertices, edges and so on, turn on Snap (page 2–35) with the appropriate snap settings activated.

2. Move either end to a new location. The line between stretches to the new distance, shown in the Length field.

   Note: For accurate results when moving a tape endpoint with Snap, you must turn on Pivot in the Snap Settings panel as well as the types of sub-object you want to snap to; see Snaps (page 2–41). This is because the endpoints are actually pivots.

To set a distance:
- Turn on Specify Length in the Parameters rollout, enter a length, and then create the tape.

   The connector line is the length you specified, although you can still set the target to any offset by dragging. You can reorient this line as required.

   Note: Clearing Specify Length will adjust the connector line length to meet the target and the new length appears in the Length field.

Interface

Parameters rollout

Length—Specifies the length of the tape object. You must select the Specify Length check box to enable this option.

Specify Length—Activates the Length parameter setting. Otherwise the tape object’s length will be specified by clicking and dragging in the viewport.
World Space Angles group

To XYZ Axis—Displays the angle of the tape object relative to each axis in world space.

To XY/YZ/ZX Plane—Displays the angle of the tape object relative to each of these home planes.

Protractor Helper

Create panel > Helpers > Standard > Object Type rollout > Protractor
Create menu > Helpers > Protractor

Protractor measures the angle between a point and any two objects in your scene.

The names of the two objects appear above their respective buttons, and the angle formed at the protractor object between the pivot points of the two objects is displayed in the Angle field. Lines are drawn between the protractor and the two selected objects.

Note: The line to the first selected object uses the Target Line color, and the line for the second selected object uses the color of the protractor. The Target Line color is set with Customize User Interface dialog > Colors panel (page 3–799) > Elements drop-down list > Gizmos group. The Protractor color is set by choosing the Tape Object in Customize User Interface dialog > Colors panel (page 3–799) > Elements drop-down list > Objects group.

You can reselect the protractor at any time, enter the Modify panel (page 3–758), and pick new objects to measure. You can move either of the two objects or the protractor itself to change the angle.

Note: If you need to watch the Angle readout while moving either of the objects, first select the protractor, then click the Pin Stack button on the Modify panel. You can now select and move the other objects while the stack remains pinned to display the protractor angle.

Procedure

To use the protractor:

1. After selecting Protractor in the Create panel > Helpers section, click in the viewport to place and create the protractor icon. You can also drag to move it before releasing the mouse button.

2. Click the Pick Object 1 button, and then select one of the objects in the scene.

The name of the selected object appears above the button.

3. Click Pick Object 2, and then select a second object in the scene.

The Angle parameter shows the angle formed by lines from the protractor object to the two picked objects.

Interface

Parameters rollout

Pick Object 1—Click this and select the first of the two objects whose angle you want to measure.

Pick Object 2—Click this and select the second of the two objects whose angle you want to measure.

Angle—Displays the angle formed by the lines from the protractor to the two objects.
Compass Helper

Create panel > Helpers > Standard > Object Type rollout > Compass
Create menu > Helpers > Compass

Compass displays as a non-rendering compass rose, with indicators for North, South, East, and West. A compass is part of a Daylight or Sunlight system (page 1–418); you create a compass automatically when you create sunlight. In a Sunlight system, the orientation of the compass indicates the orientation of the scene, relative to the path of the sun (the ecliptic).

Use the Compass helper object if you want to create an orientation symbol in your scene, but don’t need to create a sunlight system.

Procedure
To create a compass object:
1. Choose Compass in the Create panel > Helpers section.
2. Click and drag to define the radius of the compass.
3. Select and rotate the compass object to orient it.

Interface

Parameters rollout

Show Compass Rose—Displays the non-rendering compass rose in the viewport.
Radius—Specifies the radius of the compass object.

Manipulator Helper Objects

Create panel > Helpers > Manipulators > Object Type rollout
Create menu > Helpers > Manipulators

Manipulator helpers are objects you can create to manipulate other objects. They let you add customized controls to your scene that provide visual feedback in viewports. To control other objects, manipulators use the parameter wiring feature (page 2–411).

Manipulators can be especially useful when you create a scene that will be used by more than one animator.

There are three kinds of manipulator helpers:
Cone Angle Manipulator (page 2–27)
Plane Angle Manipulator (page 2–29)
Slider Manipulator (page 2–31)

See also

Wire Parameters (page 2–411)
Parameter Wiring Dialog (page 2–412)
Select And Manipulate (page 2–15)

Cone Angle Manipulator

Create panel > Helpers > Manipulators > Object Type rollout > Cone Angle button
Create menu > Helpers > Manipulators > Cone Angle

The Cone Angle manipulator is a cone whose base you can adjust. By wiring its Angle value to a parameter of another object, you can create a custom control, with visual feedback, within a scene.
Cone angle manipulators are used by a spotlight’s Hotspot and Falloff controls.

**Procedures**

**To create a cone angle manipulator:**

1. ![Select Object](image)

   In the Create panel, go to Helpers and choose Manipulators from the drop-down list.

2. Click to turn on Cone Angle.

3. Drag in a viewport, and then release the mouse.

   The cone angle manipulator is created along the negative Z axis of the viewport in which you drag. In other words, its initial position points away from you.

**To change the angle of a cone angle manipulator:**

1. ![Select Object](image)

   Turn on Select And Manipulate.

   Tip: If you are still in the Create panel, turn on Select Object before using the manipulator. Otherwise, it is too easy to create a new one.

2. In a viewport, move the mouse over the manipulator.

   The manipulator turns red when the mouse is over it and it is available to be manipulated. Also, a tooltip appears, showing the name of the manipulator and its current value.

3. Drag the base of the cone angle manipulator’s cone.

   The Angle value changes as you drag the manipulator. This value can range between 0.0 and 360.0.

**To select a cone angle manipulator:**

1. ![Select Object](image)

   Turn on Select Object.

   You can also use Select And Move, Select And Rotate, and the scale options on a cone angle manipulator.

2. ![Select Object](image)

   Turn off Select And Manipulate.

   If you don’t turn off Select And Manipulate, you adjust the manipulator’s Angle value without affecting its properties.

3. ![Select Object](image)

   Adjust the properties of the selected manipulator.

**To connect a cone angle manipulator so it controls another object:**

1. ![Select Object](image)

   Select the cone angle manipulator.

   Note: Select And Manipulate must be off before you can select the manipulator.

2. ![Select Object](image)

   Choose Animation > Wire Parameters > Wire Parameters.

   You can also right-click the manipulator and choose Wire Parameters from the Transform (lower-right) quadrant of the quad menu.

   A pop-up menu appears over the manipulator.

3. ![Select Object](image)

   In the pop-up menu, choose Object > Angle.

4. ![Select Object](image)

   Drag to the object you want to manipulate, and click it.

   A pop-up menu appears over the object.
5. In the pop-up menu, choose Object, then the name of the parameter you want to manipulate. The Parameter Wiring dialog (page 2–412) appears.

6. In the Parameter Wiring dialog, make sure the direction goes from the manipulator to the object (or both directions), and then click Connect.

7. Close the Parameter Wiring dialog. Now when you turn on Select And Manipulate and use the manipulator, the object updates under the manipulator’s control.

**Plane Angle Manipulator**

The Plane Angle manipulator looks like a lever or joystick. By wiring its Angle value to a parameter of another object, you can create a custom control, with visual feedback, within a scene.

---

**Interface**

<table>
<thead>
<tr>
<th>Parameters</th>
</tr>
</thead>
<tbody>
<tr>
<td>Angle: 12.05</td>
</tr>
<tr>
<td>Distance: 158.746</td>
</tr>
<tr>
<td>Use Square: off</td>
</tr>
<tr>
<td>Aspect: 1.0</td>
</tr>
</tbody>
</table>

**Angle**—The initial angle of the manipulator.

**Distance**—The length of the manipulator, in 3ds Max units. Default=the distance of mouse drag when the manipulator was created.

**Use Square**—When on, the base of the cone is square or rectangular, rather than circular. Default=off.

**Aspect**—When Use Square is on, adjusts the aspect ratio of the rectangular cone base. Default=1.0.

---

*Plane angle manipulator at different angles*
Procedures

To create a plane angle manipulator:

1. In the Create panel, go to Helpers and choose Manipulators from the drop-down list.
2. Click to turn on Plane Angle.
3. Drag in a viewport, and then release the mouse.
   The plane angle manipulator is always created vertically, along the Y axis of the viewport in which you drag.

To change the angle of a plane angle manipulator:

1. Turn on Select And Manipulate.
   Tip: If you are still in the Create panel, turn on Select Object before using the manipulator. Otherwise, it is too easy to create a new one.
2. In a viewport, move the mouse over the manipulator.
   The manipulator turns red when the mouse is over it and it is available to be manipulated. Also, a tooltip appears, showing the name of the manipulator and its current value.
3. Drag the handle of the plane angle manipulator.
   The Angle value changes as you drag the manipulator. This value can range between 0.0 and 360.0.

To select a plane angle manipulator:

1. Turn on Select Object.
   You can also use Select And Move, Select And Rotate, and the scale options on a plane angle manipulator.

2. Turn off Select And Manipulate.
   If you don't turn off Select And Manipulate, you adjust the manipulator’s Angle value without affecting its properties.
3. Adjust the properties of the selected manipulator.

To connect a plane angle manipulator so it controls another object:

1. Select the plane angle manipulator.
   Note: Select And Manipulate must be off before you can select the manipulator.
2. Choose Animation > Wire Parameters > Wire Parameters.
   You can also right-click the manipulator and choose Wire Parameters from the Transform (lower-right) quadrant of the quad menu.
   A pop-up menu appears over the manipulator.
3. In the pop-up menu, choose Object > Angle.
4. Drag to the object you want to manipulate, and click it.
   A pop-up menu appears over the object.
5. In the pop-up menu, choose Object, then the name of the parameter you want to manipulate.
   The Parameter Wiring dialog (page 2–412) appears.
6. In the Parameter Wiring dialog, make sure the direction goes from the manipulator to the object (or both directions), and then click Connect.
7. Close the Parameter Wiring dialog.
   Now when you turn on Select And Manipulate and use the manipulator, the object updates under the manipulator’s control.
Interface

<table>
<thead>
<tr>
<th>Parameters</th>
</tr>
</thead>
<tbody>
<tr>
<td>Angle: 0.0</td>
</tr>
<tr>
<td>Distance: 360.0</td>
</tr>
<tr>
<td>Size: 1.0</td>
</tr>
</tbody>
</table>

**Angle**—The angle of the manipulator, from 0.0 to 360.0 (both values are perpendicular in the Y axis of the viewport where you created the manipulator, unless you have rotated the manipulator object). Default=0.0.

**Distance**—The length of the manipulator, in 3ds Max units. Default=the distance of mouse drag when the manipulator was created.

**Size**—The size of the manipulator’s handle, in 3ds Max units. Default=1.0.

---

### Slider Manipulator

Create panel > Helpers > Manipulators > Object Type rollout > Slider button

Create menu > Helpers > Manipulators > Slider

The Slider manipulator is a graphic control that appears in the active viewport. By wiring its Value to a parameter of another object, you can create a custom control, with visual feedback, within a scene.

Note: Because the slider manipulator is a custom control, its Value has no inherent unit. It takes on the unit of the parameter to which it is wired. When the minimum is 0.0 and the maximum is 100.0, the slider Value can represent a percentage.

---

### Using a Slider Manipulator

The slider appears in the same location in whichever viewport is active.

You can adjust the slider’s value by dragging the triangle below the slider bar. The triangle turns red when you move the mouse over it. It represents the slider’s value, and the value changes as the triangle is dragged. You can also make the following changes without going into the Modify panel:

- Dragging the small square at the left moves the slider.
- Dragging the diamond at the right changes the width of the slider.
- Clicking the plus sign (next to the move icon at the left) hides all of the slider except for the label and the move icon.

Like the Value triangle, these components also turn red when you move the mouse over them.

---

Slider manipulator
Procedures

To create a slider manipulator:

1. In the Create panel, go to Helpers and choose Manipulators from the drop-down list.
2. Click to turn on Slider.
3. Click a viewport.

The slider manipulator is created with its default width of 100 units. It will appear at the same viewport location in whichever viewport is active.

To change the value of a slider manipulator:

1. Turn on Select And Manipulate.
   The slider turns green.
   Tip: If you are still in the Create panel, turn on Select Object before using the manipulator. Otherwise, it is too easy to create a new one.
2. In a viewport, move the mouse over the triangle below the slider bar.
   The triangle turns red when the mouse is over it and it is available to be dragged.
3. Drag the value triangle of the slider manipulator.
   The slider’s value display changes as you drag the triangle.

To move a slider manipulator:

1. Turn on Select And Manipulate.
2. In the active viewport, move the mouse over the move icon, which is the small square at the left of the slider, below the sliders label (if there is one) and value display.

   The square turns red when the mouse is over it and it is able to be dragged.
3. Drag the box to move the slider.
   Unlike angle manipulators, transforms have no effect on sliders.

To connect a slider manipulator so it controls another object:

1. Select the slider.
   Note: Select And Manipulate must be off before you can select the slider.
2. Choose Animation > Wire Parameters > Wire Parameters.
   You can also right-click the manipulator and choose Wire Parameters from the Transform (lower-right) quadrant of the quad menu.
   A pop-up menu appears over the manipulator.
3. In the pop-up menu, choose Object > Value.
4. Drag to the object you want to manipulate, and click it.
   A pop-up menu appears over the object.
5. In the pop-up menu, choose Object, then the name of the parameter you want to manipulate.
   The Parameter Wiring dialog (page 2–412) appears.
6. In the Parameter Wiring dialog, make sure the direction goes from the slider to the object (or both directions), and then click Connect.
7. Close the Parameter Wiring dialog.
   Now when you turn on Select And Manipulate and use the slider, the object updates under the slider’s control.
Grid Commands

Views menu > Grids

The Grids submenu provides functions to manipulate the home grid (page 3–952) and grid objects (page 3–951).

The Snaps system uses grids both as visual references and as physical snap references. In addition, grids serve as construction planes, since the objects you create are built on the active grid in the active viewport.

As a default, the software uses a construction grid called the home grid. The home grid is the basic reference system, and is defined by three fixed planes on the world coordinate axes. It provides ready-to-use construction planes, intersecting at right angles through the origin. When the home grid is displayed, each orthographic viewport (page 3–986) is coplanar (parallel) with one of the grid faces.

A custom grid, or grid object, is a helper object that you can use in place of the home grid. While the home grid is three intersecting planes whose orientation is fixed in world space, a grid object is a free-floating, 2D grid that you can position and rotate anywhere, letting you construct objects at any angle in world space. You can also automatically create grids on the surface of objects by using AutoGrid (page 2–7).

The Grids submenu contains the following commands:

**Interface**

- **Label**—The slider name that appears in viewports. Default=none.
- **Value**—The value of the slider, based on the position of the slidable triangle. Default=0.0.
- **Minimum**—The minimum possible value of the slider. Default=0.0.
- **Maximum**—The maximum possible value of the slider. Default=100.0.

When the minimum is 0.0 and the maximum is 100.0, the slider Value can represent a percentage.

- **X Position**—The slider’s X location in the active viewport. Default=Viewport X location you clicked when you created the slider.
- **Y Position**—The slider’s Y location in the active viewport. Default=Viewport Y location you clicked when you created the slider.
- **Width**—The slider’s width, in 3ds Max units. Default=100.0.
- **Snap**—When on, the slider "snaps" to incremental values determined by the Snap Value setting. Default=on.
- **Snap Value**—The increment used by the slider when Snap is on. Default=0.01.
- **Hide**—When on, hides all of the slider except for the label and the move and show/hide components. Default=off.

---

**Grid Commands**

The Grids submenu provides functions to manipulate the home grid (page 3–952) and grid objects (page 3–951).

The Snaps system uses grids both as visual references and as physical snap references. In addition, grids serve as construction planes, since the objects you create are built on the active grid in the active viewport.

As a default, the software uses a construction grid called the home grid. The home grid is the basic reference system, and is defined by three fixed planes on the world coordinate axes. It provides ready-to-use construction planes, intersecting at right angles through the origin. When the home grid is displayed, each orthographic viewport (page 3–986) is coplanar (parallel) with one of the grid faces.

A custom grid, or grid object, is a helper object that you can use in place of the home grid. While the home grid is three intersecting planes whose orientation is fixed in world space, a grid object is a free-floating, 2D grid that you can position and rotate anywhere, letting you construct objects at any angle in world space. You can also automatically create grids on the surface of objects by using AutoGrid (page 2–7).

The Grids submenu contains the following commands:
Chapter 10: Precision and Drawing Aids

Show Home Grid (page 2–34)
Activate Home Grid (page 2–34)
Activate Grid Object (page 2–34)
Align Grid to View (page 2–35)

Show Home Grid
Views menu > Grid > Show Home Grid
Right-click a viewport label. > Show Grid
Keyboard > G

Show Home Grid toggles the display of the home grid (page 3–952) in the active viewport.

Grids are used both as visual references and as physical snap references by the Snap system. In addition, grids are construction planes, since the objects you create are built on the active grid in the active viewport.

As a default, there is a home construction grid called home grid. The home grid is the basic reference system, and is defined by three fixed planes on the world coordinate axes. It provides ready-to-use construction planes, intersecting at right angles through the origin. When the home grid is displayed, each orthographic viewport (page 3–986) is coplanar (parallel) with one of the grid faces.

Procedure
To toggle the display of the home grid, do one of the following:

- Choose Views menu > Grids, and click Show Home Grid.
- Right-click a viewport label and click Show Grid on the viewport right-click menu.
- Press G on the keyboard.

Activate Home Grid
Activate a grid other than the Home grid. > Views menu > Grids > Activate Home Grid

This command activates the home grid (page 3–952) as the construction grid, and deactivates the active grid object (page 3–951).

Procedure
To return to the home grid, do one of the following:

- Choose Views menu > Grids > Activate Home Grid.
- Right-click the selected grid object, and choose Activate Home Grid from the quad menu.

This deactivates the grid object and activates the home grid in all views.

Activate Grid Object
Select a grid object. > Views menu > Grids > Activate Grid Object

This command activates the selected grid object (page 3–951) as the construction grid and deactivates the home grid (page 3–952). This menu item is available only when a grid object is selected.

Procedure
To activate a grid object:
1. Select a grid object.
2. Do one of the following:
   - Choose Views menu > Grids > Activate Grid Object.
   - Right-click the selected grid object and choose Activate Grid from the quad menu.

The grid object changes to show its internal grid structure. Except for its main axes, the home grid disappears in all viewports.
Align Grid to View

Activate a grid object. > Views menu > Grids > Align Grid to View

This command aligns a grid object (page 3–951) with the current view. The grid object is aligned so that it’s coplanar with the view and oriented with the top of the grid at the top of the view.

Procedure

To align a grid object with a viewport:

1. Activate a grid object.
2. Click or right-click in a viewport.
3. Choose Views menu > Grids > Align Grid to View.

The grid object rotates to align itself with the selected view. The grid object is now planar, or parallel, with the viewport.

Snap Commands

main toolbar > Snap buttons

Snaps help you precisely control the dimensions and placement of objects when you create them or transform them. There is also a Spinner snap for controlling the entry of values.

You can use objects within an XRef scene as snap references.

The snap commands listed below and described in this section are found on the main toolbar (except for Ortho and Polar; see their topics for details).

The buttons on the Snaps Toggle flyout provide control over the range of 3D space where snaps are active.

Object Snapping

Object snapping lets you snap to specific portions of existing geometry during creation and transforms of objects or sub-objects. You can also snap to the grid, and you can snap to tangents, midpoints, pivot points, face centers and other options.

The mode you choose maintains its state when you switch levels.
Transforming Around Snap Points
When snapping is on and Auto Key (page 3–717) is off, rotations and scales occur about the snap point. For example, if you're using Vertex snapping and you're rotating a box, you can rotate it about any of its corner vertices. See To use snaps to move an absolute distance: (page 2–36) below.

When Auto Key is on and either Select And Rotate or Select And Scale is active, the Snaps Toggle button is disabled, and rotation and scaling take place about the pivot point of the object.

Relative and Absolute Snaps
The mouse snaps absolutely to the active snap types. Relative snapping is also available. By default, when you turn on snaps, only the Grid Points snap type is active. If you perform a Move operation, the cursor will snap to the grid, but you can select and pick up an object that's not aligned to the grid. When you move the object and snap it to grid points, the object's original position relative to the grid is maintained as an offset to each grid point, providing relative snapping.

To move the same object in an absolute fashion, add the Vertex snap type. Then, when you select the object to move, you select one of its vertices, and snap that vertex to any grid point, resulting in an absolute snap.

You can also achieve variations on relative snaps by turning on the Selection Lock Toggle button in the status line.

A wide variety of snap types are available from the Snaps dialog (page 2–41), that you use to activate different snap types as you work.

Procedures
To turn snap off during a transform:
• Press $S$ to toggle snapping off when it gets in the way. Press $S$ again to turn it back on.

To use snaps to move a relative distance:
1. Turn on Snaps with the $S$ key, or by clicking the Snaps Toggle button.
2. Lock your selection set with the SPACEBAR, or by clicking Lock Selection on the status bar.
3. Wherever you click in the viewport, the snap will stay relative to the distance of your cursor to the object.

To use snaps to move an absolute distance:
1. Turn on Snaps Toggle.
2. Click the selection. Snap uses the point you click for the snap source.
3. Move to whatever target snap you desire. The object will snap to an absolute distance.

To rotate a box around a vertex using snaps:
1. Make sure the Auto Key button is off.
2. Select the box.
3. On the Main toolbar, click Select And Rotate.
4. Turn Snaps on by pressing $S$ on the keyboard.
5. On the Customize menu, choose Grid And Snap Settings. Turn on Vertex and turn off Grid Points.
7. On the toolbar, choose Use Transform Coordinate Center (hold the mouse down on Use Pivot Point Center to expose the flyout).
8. Move your cursor over any vertex in the box. The blue snap cursor will appear, and then you can rotate the box around that vertex.

Interface
There are three snap modes:
2D Snap—The cursor snaps only to the active construction grid, including any geometry on the plane of that grid. The Z axis, or vertical dimension, is ignored.

2.5D Snap—The cursor snaps only to the vertices or edges of the projection of an object onto the active grid.

Suppose you create a grid object (page 3–951) and make it active. You then position the grid object so you can see through the grid to a cube further off in 3D space. Now with 2.5D set, you can snap a line from vertex to vertex on the distant cube, but the line is drawn on the active grid. The effect is like holding up a sheet of glass and drawing the outline of a distant object on it.

3D Snap—This is the default. The cursor snaps directly to any geometry in 3D space. 3D snapping lets you create and move geometry in all dimensions, ignoring the construction plane.

Right-click this button to display the Grid and Snap Settings dialog (page 2–41), while you change snap categories and set other options.

Angle Snap Toggle

Main toolbar > Angle Snap Toggle
Keyboard > A

Angle Snap Toggle determines the incremental rotation for a number of features, including the standard Rotate transform. As you rotate an object (or group of objects), the object moves around a given axis in the increment you set.

Angle Snap Toggle also affects Pan/Orbit camera controls, FOV (page 3–937) and Roll camera settings, and Hotspot/Falloff (page 3–954) spotlight angles.

Procedures

To turn angle snap on:
- Click Angle Snap Toggle on the Main toolbar. When turned on, angle snap affects all rotational transforms.

To rotate an object an even number of degrees:
- Turn on Angle Snap Toggle and rotate the object.
  The rotations take place in 5-degree increments as a default.

To rotate an object a precise degree of rotation, do one of the following:
- Click Select And Rotate, then right-click it to display the Transform Type-In dialog (page 1–431). Enter the exact rotation you want.
- Right-click Angle Snap Toggle and click the Options tab on the dialog that is displayed. Set the Angle value in the General group to the precise degree of rotation you need, then rotate the object. Rotation snaps to the angle increment you specified.

Interface

The angle increment is set on the Options panel of the Grid and Snap Settings dialog (page 2–41). Right-click the Angle Snap Toggle button to display the Options panel of the Grid and Snap Settings dialog. The default is 5 degrees.
Percent Snap Toggle

Main toolbar > Percent Snap Toggle

Keyboard > Ctrl+Shift+P

Percent Snap Toggle increments scaling of objects by the specified percentage.

**Interface**

The snap percent increment is set in the Grid And Snap Settings dialog. The default is 10 percent. Right-click the Percent Snap Toggle button to display the Grid and Snap Settings dialog (page 2–41).

This is a general-purpose snap system that applies to any operation involving a percentage, such as scaling or squashing.

Spinner Snap Toggle

Main toolbar > Spinner Snap Toggle

Spinner Snap Toggle sets the single-click increment or the decrement value for all of the spinners in 3ds Max.

**Procedure**

**To set and toggle spinner snap:**

1. Do one of the following:
   - Choose Customize menu > Preferences.
   - Right-click the Spinner Snap Toggle button on the main toolbar.
   - Either method opens the Preference Settings dialog > General panel. The two controls for spinner snap are in the Spinners group on this panel.

2. Set a value in the Snap field.

3. Turn on Use Snap.

   When you exit the dialog, the Spinner Snap Toggle button is turned on.

4. As you work, use the Spinner Snap Toggle button to toggle the alternate setting.

**Interface**

The amounts for Spinner Snap are controlled by settings on the *General panel* (page 3–815) of the Preferences dialog. Default=1.0.

Ortho Snapping Mode

When drawing a Line spline (page 1–270) or Wall object (page 1–223), Ortho Snapping Mode constrains line creation to the horizontal or vertical directions relative to the active grid. That is, with Ortho on, you can draw only lines that are parallel to lines of the active grid. Ortho is particularly useful for drawing plans where all lines must be at 90 degrees to each other, such as a house plan. To constrain line-drawing to other angle increments, use Polar Snapping Mode (page 2–39) instead.

**Important:** By default, Ortho Snapping Mode is not directly accessible in the 3ds Max user interface. To add it as a button on the Snaps toolbar, follow *this procedure* (page 2–39).

The following provisions apply to using Ortho:

- Use of Ortho is mutually exclusive of use of the Polar Snapping Mode toggle (page 2–39); only one can be active at a time.
- Ortho Snapping applies primarily to the creation of line splines and wall objects. It can be used while creating other objects, but results are likely to be unsatisfactory.

Ortho mode displays a compass which gives a readout of the current angle of the input relative to the positive direction of the local X axis.
Note: If you hold down the [Alt] key in Ortho mode, the next point becomes doubly constrained by both the previous point and the first point of the current object. This allows you to close splines precisely. In this mode, two compasses are displayed; one each at the first and previous points.

Procedures

To add Ortho Snapping Mode to the Snaps toolbar:
1. Open the Snaps toolbar, if necessary. To do so, right-click an empty part of the main toolbar, such as the area directly below one of the drop-down lists, and choose Snaps.
2. Drag the right end of the toolbar to the right to make room for a new button.
3. Choose Customize menu > Customize User Interface.
   This opens the Customize User Interface dialog.
4. On the dialog, click the Toolbars tab.
5. Scroll down the Action list on the dialog to the Ortho Snapping Mode item. You can jump to the O section by clicking any item in the list and then pressing [O] on the keyboard.
6. Drag the Ortho Snapping Mode item from the list to the empty section of the Snaps toolbar. This adds the button to the toolbar.
7. Close the Customize User Interface dialog.
   3ds Max automatically saves the toolbar in its revised state and makes the new button a permanent part of the user interface.

To use Ortho:
1. Turn on the Ortho Snapping Mode button.
   The button appears depressed.
2. Begin to draw a Line spline.
   An orange compass appears where you place the first point, along with a red number indicating the angle of the current line segment with the positive direction of the local X axis.
3. Move the mouse cursor around in the viewport.
   The line jumps to 90-degree angle increments on the local X axis, while the compass reading updates to show the current angle.
4. Click to place the next vertex.
5. Repeat steps 3 and 4 until you’re ready to complete the shape.
6. Do either of the following:
   • To finish the shape at the most recent vertex without closing it, right-click anywhere.
   • To finish the shape by closing it, position the mouse cursor close to the first point and then click. A small dialog opens asking if you want to close the spline; click Yes.

Polar Snapping Mode

When drawing a Line spline (page 1–270) or Wall object (page 1–223), Polar Snapping Mode constrains line creation to angle increments determined by the Angle Snap setting relative to the active grid. To change the Angle Snap setting, right-click the Angle Snap Toggle button on the main toolbar and in the Options panel > General group, edit the Angle setting.

Important: By default, Polar Snapping mode is not directly accessible in the 3ds Max user interface. To add it as a button on the Snaps toolbar, follow this procedure (page 2–40).

Polar is particularly useful for drawing plans where angles between all lines must conform to specific angle increments, such as 45 degrees. If all lines must be at 90-degree angles to each other, use the Ortho Snapping Mode toggle (page 2–38) instead.

The following provisions apply to using Polar:
• Use of Polar is mutually exclusive of use of the Ortho toggle; only one can be active at a time.
• Polar applies primarily to the creation of line splines and wall objects. It can be used while creating other objects, but results are likely to be unsatisfactory.

Polar mode displays a compass that provides a readout of the current angle of the input relative to the positive direction of the local X axis.

Note: If you hold down [Alt] in Polar mode, the next point becomes doubly constrained by both the previous point and the first point of the current object. This allows you to close splines precisely. In this mode, two compasses are displayed; one each at the first and previous points.

Procedures

To add Polar Snapping Mode to the Snaps toolbar:

1. Open the Snaps toolbar, if necessary. To do so, right-click an empty part of the main toolbar, such as the area directly below one of the drop-down lists, and choose Snaps.
2. Drag the right end of the toolbar to the right to make room for a new button.
3. Choose Customize menu > Customize User Interface.
   This opens the Customize User Interface dialog.
4. On the dialog, click the Toolbars tab.
5. Scroll down the Actions list on the dialog to the Polar Snapping Mode item. You can jump to the P section by clicking any item in the list and then pressing [P] on the keyboard.
6. Drag the Polar Snapping Mode item from the list to the empty section of the Snaps toolbar. This adds the button to the toolbar.
7. Close the Customize User Interface dialog.

3ds Max automatically saves the toolbar in its revised state and makes the new button a permanent part of the user interface.

To use Polar:

1. Turn on the Polar Snapping Mode button. The button appears depressed.
2. Begin to draw a line spline.
   An orange compass appears where you place the first point, along with a red number indicating the angle of the current line segment with the positive direction of the local X axis.
3. Move the mouse cursor around in the viewport.
   The line jumps to specific angle increments from the X-axis, while the compass reading updates to show the current angle. You set the angle increment in the Grid And Snap Settings dialog > Options panel (page 2–46) > General group, which you can access by right-clicking the Angle Snap Toggle button on the main toolbar.
4. Click to place the next vertex.
5. Repeat steps 3 and 4 until you’re ready to complete the shape.
6. Do any of the following:
   • To finish the shape at the most recent vertex without closing it, right-click anywhere.
   • To finish the shape by closing it, position the mouse cursor close to the first point and then click. A small dialog opens asking if you want to close the spline; click Yes.
   • To finish the shape by closing it while constraining the line to the polar snap, first position the mouse cursor close to the first point, press and hold [Alt] to constrain the mouse by both the previous point and the first point, and then click. This vertex is automatically placed at the current angle increment from the first point, so that you need only click the first point to close the shape.
Grid and Snap Settings

This command displays the Grid and Snap Settings dialog. This modeless dialog establishes settings and options for snaps, the home grid (page 3–952), and user-defined grids.

Controls on the Grid And Snap Settings dialog determine which snap settings are used when you activate snaps by clicking 3D Snap Toggle. Adjusting any of these snap settings does not automatically turn on snaps.

You can use objects within an XRef scene as snap references.

The Grid And Snap Settings dialog contains tabs for:

- Snap Settings (page 2–41)
- Snap Options (page 2–46)
- Home Grid Settings (page 2–49)
- User Grids Settings (page 2–51)

Procedure

To change grid and snap settings:

1. Choose Customize menu > Grid And Snap Settings and click the appropriate tab.
2. Choose the type of snap you want (Standard or NURBS).
3. Select the snap settings.

Snap Settings

Customize menu > Grid And Snap Settings > Grid And Snap Settings dialog > Snaps tab

Main toolbar > Right-click a snap button
Keyboard > Hold \[Shift\] right-click > Snaps quadrant
Keyboard > \[S\] (toggles snaps on and off)

Snapping gives you additional control when creating, moving, rotating, and scaling objects by causing the cursor to “jump” to specific portions of existing geometry and other scene elements during creation and transformation of objects or sub-objects. The controls in this dialog set the snap strength and other characteristics such as the snap target.

Note: Snap functionality includes several features that enhance ease of use. See the Snap Options topic (page 2–48) for details.

You can specify the portion of the geometry where you will snap. For example, when Vertex is the active snap type, creating and transforming objects snaps to the vertices of existing geometry. You can specify any combination of active snap types to provide multiple snapping points. For example, if Vertex and Midpoint are active, snapping occurs at both vertices and edge midpoints.

The default snap type is Grid Points.

Note: Snapping is not on by default. You can toggle snapping by pressing the \[S\] key at any time, even in the middle of a transform. In this way you can combine snapping with free positioning.

Snaps work at sub-object levels. For example, you can use snaps to position a gizmo to the object on which you’re working, or snap it to other objects in the scene.

You must activate a viewport in order to use snaps. Also, the Z-axis constraints don’t apply to the
home grid or grid objects, since grids don’t have a Z axis.

Settings are stored in the 3dsmax.ini (page 1–18) file. The state of the snap settings persists from session to session.

Snaps and Axis Constraints
Snaps take precedence over axis constraints. If you highlight an axis constraint, such as Restrict to X, you can move the object only in X. But if you then turn on snaps, Restrict to X is suspended and not used.

The Snaps Toolbar

The most common Snaps settings are available from an optional toolbar. To toggle display of the Snaps toolbar, right-click an empty area of the main toolbar, such as the section under the Reference Coordinate System drop-down, and choose Snaps. The toolbar buttons are shown next to the relevant commands, below and in the Snap Options topic (page 2–46).

The same settings are also available from the snap quad menu, available with Shift+right-click.

Snaps: Relative and Absolute
3ds Max offers two different types of snap behavior. You can use snaps to move a selection to a snap point, an absolute snap. You can also use snaps to move a selection a relative distance from a snap point. This is called a relative snap. For further information, see To use relative snaps: (page 2–42).

Procedures
To set grid and snap settings:
1. Turn on the 3D Snap Toggle button to activate snaps.
2. Choose Customize > Grid And Snap Settings to display the Grid and Snap Settings dialog.
3. In the Snaps tab, select one or more of the types of snaps you want active.
4. Create an object or transform an object.

Snap markers appear when the mouse cursor is over existing geometry or on a grid, depending on the active snap types. Each snap type has a different display; clicking when the snap-specific display is visible snaps to that spot.

To display the Snaps shortcut menu:
- Hold Shift and right-click anywhere in any viewport. The quad menu that opens gives you access to various snap settings including Snaps Use Axis Constraints and Snap To Frozen Objects.

To use absolute snaps:
- Click the object with Snaps on.

To use relative snaps:
1. Lock the selection set.
2. Click in the viewport.

The distance from your cursor to the selection set is used as the relative snap distance. The object snaps that relative distance away from the snap point.

To use both constraint and snaps, do one of the following:
- In the Grid and Snap Settings dialog > Options tab > Translation group, turn on Use Axis Constraints.
• Hold [Shift] and right-click in the viewport, and then choose Options > Transform Constraints from the Snap quadrant.

**Example: To use 3D snaps and rotation transformations together:**

1. Create a box.
2. Select the box and choose Lock Selection.
3. Turn on 3D Snaps and click Rotate on the toolbar.
4. From the Use Center flyout on the main toolbar, choose *Use Transform Coordinate Center* (page 1–447).
5. Activate the Perspective viewport and move the cursor over the grid.
   A blue icon displays when the cursor passes over a grid point.
6. When the blue icon displays, click and drag to rotate the box around the selected grid point.
   You can rotate around anything you can snap to.

**To turn snaps on and off during an operation:**

• Use the [S] keyboard shortcut to turn snap on and off.

  Tip: You can select something with snap off, and then turn snap on to snap it to a snap target. Alternately you might want to snap to something, then position it freely wherever you want.

**Interface**

Use these check boxes on the Snaps tab to turn on any combination of snap settings.

After setting snaps, close the dialog using the Close button in the dialog’s upper-right corner. Do not click the Clear All button, or you’ll turn off all the snaps.

**Override**—This label changes to display the temporary snap type used by the Override system. For more information, see *Snap Override* (page 2–45).

**Clear All**—Turns off all of the Snaps check boxes.

Note: The layout of the Grid And Snap Settings dialog is generated at runtime. Because of this, it might appear slightly different than the illustrations shown here.

**Standard snaps**

These are the standard snap types used for grids, mesh, and shape objects. Non-grid snap types, when active, take priority over Grid Points and Grid Lines snaps: if the mouse is equally near a grid point and some other snap type, it will choose the other snap type.

Note: The button images shown below are from the Snaps toolbar (page 2–42).

**Grid Points**—Snaps to grid intersections.

This snap type is on by default. Keyboard shortcut= [Alt+F5]

**Grid Lines**—Snaps to any point on a grid line.

**Pivot**—Snaps to pivot points of objects.

Keyboard shortcut= [Alt+F6]
Chapter 10: Precision and Drawing Aids

**Bounding Box**—Snaps to one of the eight corners of an object’s bounding box.

**Perpendicular**—Snaps to the perpendicular point on a spline, relative to the previous point.

**Tangent**—Snaps to a tangent point on a spline, relative to the previous point.

**Vertex**—Snaps to vertices of mesh objects or objects that can be converted to editable meshes. Snaps to segments on splines. Keyboard shortcut—Alt+F7

**Endpoint**—Snaps to the end points of edges on meshes or spline vertices.

**Edge/Segment**—Snaps anywhere along edges (visible or invisible) or spline segments. Keyboard shortcut—Alt+F10

**Midpoint**—Snaps to the middle of edges on meshes and spline segments. Keyboard shortcut—Alt+F9

**Face**—Snaps anywhere on the surface of a face. Back faces are culled, so they have no effect. Keyboard shortcut—Alt+F11

**Center Face**—Snaps to the center of triangular faces.

**NURBS Snaps**

<table>
<thead>
<tr>
<th>NURBS Snaps</th>
<th>NURBS Snaps</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>CV</strong></td>
<td><strong>Point</strong></td>
</tr>
<tr>
<td><strong>Curve Center</strong></td>
<td><strong>Curve Normal</strong></td>
</tr>
<tr>
<td><strong>Curve Tangent</strong></td>
<td><strong>Curve Edge</strong></td>
</tr>
<tr>
<td><strong>Curve End</strong></td>
<td><strong>Surf Center</strong></td>
</tr>
<tr>
<td><strong>Surf Normal</strong></td>
<td><strong>Surf Edge</strong></td>
</tr>
</tbody>
</table>

These options snap to objects or sub-objects in a **NURBS model (page 3–980)**.

The NURBS snaps settings are aids for creating and transforming objects, and are not constraints. The software does not maintain the relationship between the NURBS object and other objects you create or transform.

**CV**—Snaps to a **CV sub-object (page 3–926)** in a **NURBS curve (page 3–980)** or **NURBS surface (page 3–981)**.

**Point**—Snaps to a **point sub-object (page 3–995)** in a NURBS model.

**Curve Center**—Snaps to the center of a NURBS curve.

The center of a NURBS curve is calculated parametrically, and might not be the same as the curve’s apparent visual center.

**Curve Normal**—Snaps to a point normal to a NURBS curve.

This snap operates only while you are creating a new object that requires two or more clicks to create.

**Curve Tangent**—Snaps to a point tangent to a NURBS curve.

This snap operates only while you are creating a new object that requires two or more clicks to create.

**Curve Edge**—Snaps to the edge of a NURBS curve (the current object moves or is created to lie along the curve).

**Curve End**—Snaps to the end of a NURBS curve.

**Surf Center**—Snaps to the center of a NURBS surface.

The center of a NURBS curve is calculated parametrically, and might not be the same as the curve’s apparent visual center.
Snap Override

Surf Normal—Snaps to a point on a NURBS surface normal to previous point.

This snap operates only while you are creating a new object.

Surf Edge—Snaps to the edge of a NURBS surface.

Snap Override

Any viewport > Hold \( \text{Shift} \) and right-click. > Standard > Choose snaps type.

Customize menu > Grid and Snap Settings > Snaps tab

Snap Override lets you supersede all the currently selected snap types and temporarily use only one, or none, of the snap types currently selected on the Grid and Snap Settings dialog. For example, you might be creating a spline while snapping to grid points, but then need to snap one of its vertices to the midpoint of an object.

Tip: You can choose the override by cycling through active snap types via a keyboard shortcut instead of using the quad menu. Press \( \text{Alt+S} \) repeatedly to choose the override snap type. If the Grid and Snap dialog is displayed, the "Override OFF" label changes to display the selected snap type.

Procedures

To use Snap Override (keyboard shortcut method):

1. Activate all the snap types you want to use or override with.

2. Make sure the Grid And Snap Settings dialog is open to the Snaps panel, so you can easily track the override type. Alternatively, if you're using only snap types available on the Snaps toolbar (page 2–42), you can keep the toolbar open instead.

3. While creating or moving an object with Snap on, press \( \text{Alt+S} \) repeatedly.

The Grid And Snap Settings dialog > "Override OFF" label changes to display the first available override snap type, chosen from the active snap types. If the Snaps toolbar is open, and the override snap type is available on the toolbar, the override snap type is visible there as well.

4. Press \( \text{Alt+S} \) repeatedly.

The software cycles through all the active snap types for the override type.

The benefit of this method is that it's fast and easy; you don't have to use the quad menu. But if you want to override with a snap type that isn't currently active, it's necessary to use the standard override method, which is described in the next procedure.

To use Snap Override (standard method):

1. While creating or moving an object with Snap on, hold down \( \text{Shift} \) and right-click in a viewport.

2. Select one of the snap types from the sub-menus in the Snap Override quadrant to make it the only active snap type.

If the Grid And Snap Settings dialog is open to the Snaps panel, the "Override OFF" label changes to display the active snap override type. When you complete the mouse action, "Override OFF" is again displayed in the dialog, and the previously active snap types are active again.

To use Snap Override during a drag operation:

1. Left-click, press \( \text{Shift} \) and then right-click to display the menu.

2. Release the left mouse button, and then left-click to select the snap you want.

3. Release the \( \text{Shift} \) key, right-click, and continue the drag operation (the geometry remains locked to the mouse).

4. Left-click to complete the operation.
Interface

In addition to the available snap types, the snap quad menu contains these items:

**Snap Options quadrant**—Lets you set the following options:

- **Grid and Snap Settings**: Toggles display of the Grid And Snap Settings dialog.
- **Snaps To Frozen Objects**: Turn this on to enable snapping to frozen objects. Default=off.
- **Snaps Use Axis Constraints**: Turn this on to use the current transform constraints. For example, if you’re moving a vertex with Restrict To XY Plane on and want to snap the vertex to a point removed on the Z axis, turn this off, if necessary. Default=off.

**Snap Override quadrant**—Lets you set the following options:

- **NURBS/Standard**—Let you choose a snap type for one-time use. This applies to the next snap only.
- **None**—Turns off all snap types for the next mouse action. (This item is unavailable if the Snap Toggle is off.)
- **[last]**—Displays the last snap override type you chose from the NURBS or Standard submenu, letting you easily reuse that type.

**Snap Toggles quadrant**—Lets you set six of the most common snap types on an ongoing basis. These remain in effect until you turn them off; it’s the same as setting them on the Grid And Snap Settings dialog.

**Snap Options**

Customize menu > Grid and Snap Settings > Grid and Snap Settings dialog > Options panel

Main toolbar > Right-click 3D Snap Toggle > Grid and Snap Settings dialog > Options panel

The Options panel of the Grid And Snap Settings dialog lets you set options related to snapping.

**Procedures**

**To set snap options:**

1. Choose Customize menu > Grid And Snap Settings.
2. Click the Options tab.
3. Set the options as desired.

**Example: To use Snap Preview:**

The Snap Preview Radius setting lets you preview a snap before it actually happens. The Snap Radius setting determines when actual snapping occurs, providing the same functionality as Snap Strength in previous versions.

This procedure also demonstrates how to cycle through available snap/preview points with the keyboard shortcut.

1. Reset the software, and then maximize the Perspective viewport.
   - To maximize the Perspective viewport, make sure it’s active (yellow border), and then press **Alt+W**
2. Zoom in a bit so the grid squares are relatively large.
   - Snap and Snap Preview measure in pixels, so if the grid points are relatively far apart, it’s easy to see the difference between Snap Preview and Snap.
3. On the main toolbar, click the Snaps Toggle button to turn on snapping, and then right-click the button to open the Grid And Snap Settings dialog to the Snaps panel. The default Snaps setting is Grid Points only; if this is not the case, make it so. A grid point is the intersection of two grid lines.

4. On the dialog, click the Options tab. In the General group, Snap Preview Radius is set to 30 pixels and Snap Radius is set to 20 pixels. You can leave this dialog open while you use snaps.

5. On the Create panel, click Shapes, and then click Object Type rollout > Line. You’re now in line-creation mode.

6. Click anywhere in the viewport to start creating a line-type spline object.

7. Move the cursor around the viewport. As you do so, a rubber-band line connects the mouse cursor to the start point.

8. Position the mouse cursor near a grid point, but not too close, so that the snap cursor (cyan box + crosshairs) appears at the grid point, but the line endpoint remains attached to the mouse cursor. This shows the snap preview; you’ll see its purpose in the next step.

9. Click the left mouse button. The second line vertex is created not where you clicked but at the grid point indicated by the snap preview. Snap preview lets you see where a snap will occur before it actually happens.

10. Move the cursor toward another grid point. At the Snap Preview Radius distance (30 pixels), the snap cursor appears at the grid point.

11. Continue moving the cursor toward the grid point. After you move it 10 pixels closer (the difference between Snap Preview Radius and Snap Radius), the line endpoint jumps from the mouse cursor to the grid point. This is the legacy snap functionality.

12. Click to accept the snap.

13. Complete the line, and then zoom out so the grid points are closer together. Start another line, and then position the mouse cursor in the center of a grid square, so the preview snap point appears at one of the grid points.

14. On the keyboard, press and hold [Alt+Shift] and then press [S] repeatedly to cycle through the remaining nearby grid points. If nothing happens, try zooming out more or increasing the Snap Preview Radius value. By default, the software uses the closest snap point as the preview location. This keyboard shortcut lets you choose other qualifying snap points.

**Interface**

Note: The layout of the Grid And Snap Settings dialog is generated at runtime. Because of this, it might appear slightly different than the illustration shown here.
Marker group

Provides settings that affect the visual display of the snap points.

Display—Toggles the display of the snap guides. When off, the snaps still function, but there’s no display.

Size—Sets the size, in pixels, of the snap "hit" point. This is the small icon that indicates either the source or target snap point.

Color—Click the color swatch to display the Color Selector, where you can set the color of the snap display.

General group

Snap functionality includes several features that enhance ease of use. When using Snap, if the cursor comes within distance of a potential snap point that’s less than the Snap Preview Radius distance but greater than the Snap Radius distance, the snap cursor jumps to that point as a preview of where the snap will occur, but no actual snapping occurs.

To use the preview point as the snap point, click or release the mouse button, depending on the context. If, instead, you then continue to move the cursor toward the potential snap point so that it comes within a distance equal to or less than the Snap Radius value, the snap takes place.

Tip: For best results, keep the Snap Preview Radius value 10 pixels or more higher than the Snap Radius value. This lets you preview any snap before it actually occurs.

Snap Preview Radius—When the cursor is a distance from a potential snap-to point between the Snap Preview Radius value and the Snap Radius value, the snap marker jumps to the closest potential snap-to point, but no snap occurs. Default=30.

When a snap-to preview point is highlighted, release or click the mouse button (depending on the context) to snap the current selection to that location. Alternatively, before using the displayed snap point, you can cycle though any other available preview and snap points by pressing and holding [Alt+Shift] and then press [S] repeatedly.

Note: The Snap Preview Radius value should generally be set higher than the Snap Radius value, so that previewing occurs before snapping. If you attempt to set the Snap Preview Radius value lower than the Snap Radius value, the software lowers the latter so that the two are equal. This effectively turns off previewing, so that only snapping is in effect.

Snap Radius—Sets the size of the area around the cursor, in pixels, within which snapping occurs automatically. Default=20.

Note: The Snap Radius value should generally be set lower than the Snap Preview Radius value, so that previewing occurs before snapping. If you attempt to set the Snap Radius value higher than the Snap Preview Radius value, the software raises the latter so that the two are equal. This effectively turns off previewing, so that only snapping is in effect.
**Home Grid Settings**

`Customize menu > Grid And Snap Settings > Home Grid panel`

`Main toolbar > Right-click 3D snap toggle. > Grid And Snap Settings > Home Grid panel`

The Home Grid panel of the Grid And Snap Settings dialog sets the spacing and other characteristics of the home grid (page 3–952). Choosing useful home grid settings can simplify the construction process. The home grid provides a visual reference to use when creating objects in a scene.

In the software, grids have these primary uses:

- An aid in visualizing space, scale, and distance.
- Construction planes where you create and align objects in your scene.
- A reference system for using grid snaps.

**Procedures**

**To set grid spacing for unit measure:**

1. From the menu bar, choose Customize menu > Grid And Snap Settings.
2. Click the Home Grid tab.
3. Adjust the value for Grid Spacing, which is in current units.

For example, if you have units set to centimeters, you might make one grid space equal to 1.000 (one unit, or one centimeter in this case).

**To set major grid divisions for multiple units:**

1. From the menu bar, choose Customize menu > Grid And Snap Settings.
2. Click the Home Grid tab.
3. Adjust the Major Lines Every Nth Grid Line value, which is the number of grid squares between major lines. The minimum is 2.
For example, if you use a grid spacing of one centimeter, you might use a value of 10 so the major grid divisions represent one decimeter. In perspective viewports, you can set a fixed size for the displayed home grid. If Inhibit Perspective View Grid Resize is turned off however, the grid size adjusts as you zoom in or out.

To set view update options:
1. From the menu bar, choose Customize menu > Grid And Snap Settings.
2. Click the Home Grid tab.
3. Under Dynamic Update, choose either Active Viewport (the default) or All Viewports.

To allow subdivision below grid spacing:
1. From the menu bar, choose Customize menu > Grid And Snap Settings.
2. Click the Home Grid tab.
3. Turn off Inhibit Grid Subdivision Below Grid Spacing.
   When you turn off this box, you can zoom indefinitely "deep" into any plane of the home grid. Each grid square subdivides into the same number of smaller grid spaces.

Interface
Note: The layout of the Grid And Snap Settings dialog is generated at runtime. Because of this, it might appear slightly different than the illustration shown here.

Grid Dimensions group
**Grid spacing**—Grid spacing is the size of the grid’s smallest square. Use this spinner to adjust the spacing (which is in current units), or enter the value directly.
For example, if you have units set to centimeters, you might make one grid space equal to 1.000 (one unit, or one centimeter in this case).

**Major Lines every Nth Grid Line**—The home grid displays heavier or "major" lines to mark groups of grid squares. Use spinner to adjust the value, which is the number of grid squares between major lines, or you can enter the value directly, the minimum is 2.
For example, if you use a grid spacing of one centimeter, you might use a value of 10 so the major grid divisions represent one decimeter.

**Perspective View Grid Extent**—Sets the size of the home grid in the Perspective viewport.
This value is specified in terms of the Grid Spacing value, and represents the length of half the grid along an axis. This means that if Grid Spacing=10.0 and Perspective View Grid Extent=7, you will have a grid that is 140 x 140 units in size.
**Inhibit Grid Subdivision Below Grid Spacing**—Causes 3ds Max to treat the grid as a fixed set of lines when you zoom in on the home grid. In effect, the grid stops at the grid space setting. If you keep zooming, the fixed grid is lost from view. Zooming out is not affected. When you zoom out, the home grid expands indefinitely to maintain the major grid divisions. Default=on.

When this is turned off, you can zoom indefinitely into any plane of the home grid. Each grid square subdivides into the same number of smaller grid spaces.

For a grid spacing of one centimeter and a major division of 10, the next level down subdivides into millimeter spaces, and so on.

**Inhibit Perspective View Grid Resize**—Causes 3ds Max to treat the grid in the Perspective viewport as a fixed set of lines when you zoom in or out. In effect, the grid maintains one size, no matter how much you zoom. Default=on.

When this is turned off, the grid in the Perspective viewport will subdivide to adjust its size when you zoom in or out.

**Dynamic Update group**

**Dynamic Update**—By default, only the active viewport updates as you change values for Grid Spacing and Major Lines every Nth. The other viewports update after you have completed changing the values. Choose All Viewports to have all viewports update as you change the values.

---

**Interface**

Note: The layout of the Grid And Snap Settings dialog is generated at runtime. Because of this, it might appear slightly different than the illustration shown here.

**Grid object automation group**

Determines if the software automatically makes grids active upon creation.

**Activate grids when creating**—Turn on to automatically activate the grid you created.

**Tip:** If not turned on, you can activate the grid by selecting the grid, then right-clicking and choosing Activate Grid.

**AutoGrid group**

AutoGrid allows you to automatically create grids on the surface of objects. The task of creating objects that are aligned to other object surfaces has been simplified. Turn on AutoGrid in the Object Type rollout of a command panel. When you turn on AutoGrid, the software uses the setting in the User Grids dialog for world or object space.

**World space**—Aligns grids to world space.

**Object space**—Aligns grids to object space.

---

**User Grids Settings**

Customize menu > Grid And Snap Settings > Grid And Snap Settings dialog > User Grids tab

The User Grids panel controls automatic activation of grid objects (page 2–20) and settings for AutoGrid (page 2–7).
Drawing Aid Utilities

The utilities listed here are additional aids to drawing and precision. The Measure utility returns the measurements of a selected shape or 3D object. The Rescale World Units utility rescales either a selection or an entire scene.

Use the Utilities panel (page 3–778) to open a drawing aid utility and make it active.

Measure Utility (page 2–52)
Rescale World Units Utility (page 2–53)

Measure Utility

Utilities panel > Utilities rollout > Measure button

The Measure utility provides measurements of a selected object or shape.

See also

Measure Distance Tool (page 2–15)

Procedure

To measure an object:
1. On the Utilities panel, click the Measure button.
2. Select the object you want to measure.

If both an object and a shape are in the selection, information is displayed for both types. If several objects are in a selection, the sum of their measurements is displayed.

Interface

Text display—Displays the name of the object in the current selection. If more than one object is in the selection, Multiple Objects Selected is displayed.

Lock Selected—Prevents the displayed data from changing when you change selection. For example, you might need to select and manipulate another object that affects the currently selected object.

Objects group

Displays information about renderable mesh objects.

Surface Area—Displays the total surface area of all objects in the selection, in units squared.

Volume—Displays the total volume of all objects in the selection, in units cubed. Note that objects with “holes” caused by missing faces can result in inaccurate volume values. When an object has one or more holes, an asterisk appears beside the Volume number.
Center Of Mass—Displays the world coordinates of the location of the center of mass for the object or the center of mass of the selected objects.

Create Center Point—Creates a point helper object at the center of mass.

Shapes group
Displays information about shape objects.

Length—Displays the sum of the length of all splines in all selected shapes.

Dimensions group
Displays the dimensions of the object, as they appear in world space. For example, if it were a box with the created dimensions of 15 x 10 x 25, and that box were scaled 200 percent, then this group would report dimensions of 30 x 20 x 50.

Button set
New Floater—Launches a modeless Measure dialog that displays the same information found under the Objects, Shapes, and Dimensions groups on the Utilities panel. In addition, you can expand the dialog horizontally, in case the values are too long to be viewed in the default dialog size.

Tip: While the Measure floater is displayed, you can view the length of a spline while you're creating it.

Close—Closes the utility.

Procedure
To rescale an object:
1. Select an object in the viewport.
2. On the Utilities panel, click the More button, and on the Utilities dialog, choose Rescale World Units from the list.
3. On the Rescale World Units rollout, click the Rescale button.
4. Set the Scale Factor to the desired scale. For example, setting the scale to a value of 2.0 doubles the size of the object that it's applied to.
5. In the Affect group, choose the Selection option.
6. Click OK to apply the scale.

Interface
Rescale World Units rollout

Rescale—After selecting the objects you want to rescale, click this to display the Rescale World Units dialog.

Rescale World Units dialog

Scale Factor—Specifies the scaling factor.
Affect—

• **Scene**—Applies the scale to the entire scene.

• **Selection**—Applies the scale only to the current selection.

**OK**—Applies the scale.

**Cancel**—Cancels the operation.
Space Warps and Particle Systems

Space warps and particle systems are additional modeling tools. Space warps are “force fields” that deform other objects, creating the effect of ripples, waves, blowing wind, and so on. Particle systems generate particle sub-objects for the purpose of simulating snow, rain, dust, and so on. (You use particle systems primarily in animations.)

See also
- Space Warp Objects (page 2–55)
- Particle Flow (page 2–109)
- Non-Event-Driven Particle Systems (page 2–237)

Space Warps

Create panel > Space Warps

Space warps are nonrenderable objects that affect the appearance of other objects. Space warps create force fields that deform other objects, creating the effect of ripples, waves, blowing wind, and so on.

Space warps behave somewhat like modifiers, except that space warps influence world space, rather than object space, as geometric modifiers do.

When you create a space warp object, viewports show a wireframe representation of it. You can transform the space warp as you do other 3ds Max objects. The position, rotation, and scale of the space warp affect its operation.

Surfaces deformed by space warps
- Left: Bomb
- Right: Ripple
- Rear: Wave

A space warp affects objects only when the objects are bound to it (page 2–58). The warp binding appears at the top of the object’s modifier stack. A space warp is always applied after any transforms or modifiers.
When you bind multiple objects to a space warp, the space warp’s parameters affect all the objects equally. However, each object’s distance from the space warp or spatial orientation to the warp can change the warp’s effect. Because of this spatial effect, simply moving an object through warped space can change the warp’s effect.

You can also use multiple space warps on one or more objects. Multiple space warps appear in an object’s stack in the order you apply them.

Note: You can take advantage of the AutoGrid feature to orient and position new space warps with respect to existing objects. See AutoGrid (page 2–7) for details.

**Space Warps and Supported Objects**

Some types of space warps are designed to work on deformable objects, such as geometric primitives, meshes, patches, and splines. Other types of warps work on particle systems such as Spray and Snow.

Five space warps (Gravity, PBomb, Wind, Motor, and Push) can work on particle systems and also serve special purposes in a dynamics simulation. In the latter case, you do not bind the warps to objects, but rather assign them as effects in the simulation.

On the Create panel, each space warp has a rollout labeled Supports Objects Of Type. This rollout lists the kind of objects you can bind to the warp.

**Basics of Using Space Warps**

Follow these general steps to use space warps:

1. Create the space warp.
2. Bind objects to the space warp.

Click Bind To Space Warp on the main toolbar (available from the Select And Link flyout), and then drag between the space warp and the object.

The space warp has no visible effect on your scene until you bind an object, system, or selection set to it.

3. Adjust the space warp’s parameters.
4. Transform the space warp with Move, Rotate, or Scale. The transforms often directly affect the bound object.

You can animate space warp parameters and transforms. You can also animate space warp effects by animating transforms of an object bound to the warp.

**Particle Leakage and Deflector Space Warps**

A deflector is a space warp that acts as a barrier to particles in particle systems. Occasionally stray particles can leak through a deflector under the following circumstances:

- When a particle hits the deflector too near the end or beginning of a time interval, and numerical error in the solution doesn’t report a hit
- When a particle hits too near the edge of a face referenced by a UDeflector, and neither face finds it
- When a particle is moving quickly and first appears too close to the deflector, so the very first update cycle within the particle system takes it past the deflector without the deflector ever seeing it

Often this isn’t a problem because the particles bounce off solid objects, so you don’t see the errant particles. When it does cause problems, you can use a planar deflector instead of a UDeflector, a collection of planars to approximate the mesh, or a simple mesh to replace the planar. The solutions vary, so where one has a glitch the other might work just fine.
If particles are moving fast and the deflector is in a particular position (for example, it might be too close to the emitter) many particles can leak through deflectors. Sometimes you can fix this leakage by changing the particle system’s Subframe Sampling setting or the particle speed. Other times you must reposition the deflector farther away from the emitter.

In addition, particles imbued with bubble motion (page 2–270) can leak through deflectors, particularly when set to high amplitudes. To avoid this, use alternative methods of implementing bubble-like motion, such as varying speed (see Particle Generation Rollout (page 2–260)), setting a higher angle for the stream spread with spray systems (see Spray Particle System (page 2–244), Super Spray Particle System (page 2–249)), or using larger particles with an animated texture map.

**Space Warp Categories**

There are four categories of space warps, available via the list on the Create panel’s Space Warps category.

**Forces**

These space warps are used to affect particle systems and dynamics systems. All of them can be used with particles, and some can be used with dynamics. The Supports Objects of Type rollout indications which systems each space warp supports.

- Motor Space Warp (page 2–61)
- Push Space Warp (page 2–59)
- Vortex Space Warp (page 2–63)
- Drag Space Warp (page 2–66)
- Path Follow Space Warp (page 2–71)
- PBomb Space Warp (page 2–68)
- Displace Space Warp (page 2–76)
- Gravity Space Warp (page 2–73)
- Wind Space Warp (page 2–75)

**Deflectors**

These space warps are used to deflect particles or to affect dynamics systems. All of them can be used with particles and with dynamics. The Supports Objects of Type rollout indicates which systems each space warp supports.

- PDynaFlect Space Warp (page 2–81)
- POmniFlect Space Warp (page 2–78)
- SDynaFlect Space Warp (page 2–85)
- SOmniFlect Space Warp (page 2–84)
- UDynaFlect Space Warp (page 2–86)
- UOmniFlect Space Warp (page 2–85)
- SDeflector Space Warp (page 2–87)
- UDeflector Space Warp (page 2–89)
- Deflector Space Warp (page 2–90)

**Geometric/Deformable**

These space warps are used to deform geometry.

- FFD(Box) Space Warp (page 2–91)
- FFD(Cyl) Space Warp (page 2–95)
- Wave Space Warp (page 2–100)
- Ripple Space Warp (page 2–102)
Displace Space Warp (page 2–76)
Conform Space Warp (page 2–103)
Bomb Space Warp (page 2–105)

Modifier-Based
These are space-warp versions of object modifiers (see Modify Panel (page 3–758)). Read more about these in Modifier-Based Space Warps (page 2–107).

Bend Modifier (page 1–560)
Noise Modifier (page 1–743)
Skew Modifier (page 1–790)
Taper Modifier (page 1–863)
Twist Modifier (page 1–876)
Stretch Modifier (page 1–836)

Procedure
To create a space warp:

1. On the Create panel, click Space Warps.
   The Space Warps panel is displayed.
2. Choose a category of space warp from the list.
3. On the Object Type rollout, click a space warp button.
   Tip: You can take advantage of the AutoGrid feature to orient and position new space warps with respect to existing objects. For details, see AutoGrid (page 2–7).
4. Drag in a viewport to create the space warp.
   See the topics for the various space warps for further details.

Bind to Space Warp

Main toolbar > Bind to Space Warp

Use the Bind to Space Warp button to attach the current selection to a space warp (page 3–1014) or vice versa.

Procedure
To bind the current selection to a space warp:

1. Select an object
2. Click Bind to Space Warp.
3. Drag a line from the selected object to the space warp object. You can also press H to select the space warp by name.
   The space warp object flashes for a moment to show that the bind was successful.
Forces

Push Space Warp

Create panel > Space Warps > Forces > Object Type rollout > Push
Create menu > Space Warps > Forces > Push

Push disperses a cloud of particles

The Push space warp applies a force to either particle systems (page 2–108) or dynamics systems (page 2–686). The effect is slightly different, depending on the system.

- **Particles**: Applies a uniform, unidirectional force in a positive or negative direction. A positive force moves in the direction of the pad on the hydraulic jack. The breadth of the force is infinite, perpendicular to the direction; you can limit it using the Range option.

- **Dynamics**: Provides a point force (also called a point load) away from the pad of the hydraulic jack icon. A negative force pulls in the opposite direction. In dynamics, applying a force is the same as pushing something with your finger.

Procedure

To create a Push space warp:

1. On the Create panel, click Space Warps. Choose Forces from the list, and then on the Object Type rollout, click Push.
2. Drag in a viewport to define the size. The Push warp appears as a hydraulic jack icon.
Chapter 11: Space Warps and Particle Systems

Interface

Timing group

On Time/Off Time—The numbers of the frames in which the space warp begins and ends its effect. Because Push moves the particles to which it’s applied over time, no keyframes are created.

Strength Control group

Basic Force—The amount of force exerted by the space warp.

Newtons/Pounds—This option specifies the units of force used by the Basic Force spinner.

A pound is about 4.5 Newtons, and one newton is one kilogram-per-second-squared. When Push is applied to particle systems, these values have only subjective meaning because they depend on the built-in weighting factors and time scaling used by the particle system. However, when used in a dynamics system, the value listed is precisely the value used.

Feedback On—When on, the force varies depending on the speed of the affected particles relative to the specified Target Speed. When off, the force remains constant, regardless of the speed of the affected particles.

Reversible—When on, if the particle’s speed exceeds the Target Speed setting, the force is reversed. Available only if you turn on Feedback On.

Target Speed—Specifies the maximum speed in units per frame before the Feedback takes effect. Available only if you turn on Feedback On.

Gain—Specifies how quickly the force adjusts to approaching the target speed. If set to 100 percent, the correction is immediate. If set lower, a slower and "looser" response occurs. Available only if you turn on Feedback On.

Note: Setting Gain above 100 percent can result in over-correction, but is sometimes necessary to overcome damping from other system settings, such as IK damping.

Periodic Variation group

These settings introduce variations into the force by affecting the Basic Force value randomly. You can set two waveforms to produce a noise effect.
Enable—Turns on the variations.

Period 1—The time over which the noise variation makes a full cycle. For example, a setting of 20 means one cycle per 20 frames.

Amplitude 1—The strength of the variation (in percent). This option uses the same types of units as the Basic Force spinner.

Phase 1—Offsets the variation pattern.

Period 2—Provides an additional variation pattern (a second wave) to increase the noise.

Amplitude 2—The strength of the variation of the second wave (in percent). This option uses the same types of units as the Basic Force spinner.

Phase 2—Offsets the variation pattern of the second wave.

Particle Effect Range group

Lets you restrict the Push effect’s range to a specific volume. This affects particle systems only; it has no effect on dynamics.

Enable—When on, limits the range of the effect to a sphere, displayed as a tri-hooped sphere. The effect falls off increasingly as the particles near the boundary of the sphere.

Range—Specifies the radius of the range of the effect, in units.

Display Icon group

Icon Size—Sets the size of the Push icon. This is for display purposes only, and does not alter the Push effect.

Motor Space Warp

Create panel > Space Warps > Forces > Object Type rollout > Motor

Create menu > Space Warps > Forces > Motor

Motor disperses a cloud of particles

The Motor space warp works like Push (page 2–59), but applies rotational torque to the affected particles or objects rather than a directional force. Both the position and orientation of the Motor icon affect particles, which swirl around the Motor icon. When used in dynamics, the position of the icon relative to the affected object has no effect, but the orientation of the icon does.
Procedure

To create a motor space warp:

1. On the Create panel, click Space Warps > Forces > Motor. Choose Forces from the list, then on the Object Type rollout, click Motor.
2. Click and drag in a viewport to define the size.

   The Motor warp appears as a box-shaped icon with an arrow indicating the direction of the torque.

Interface

Timing group

On Time/Off Time—The numbers of the frames in which the space warp begins and ends its effect. Because Motor moves the objects to which it’s applied over time, no keyframes are created.

Strength Control group

Basic Torque—The amount of force exerted by the space warp.

N-m/Lb-ft/Lb-in—Specify the unit of measure for the Basic Torque setting, using common world measurements of torque. N-m stands for Newton meters, Lb-ft stands for pound-force feet, and Lb-in stands for pound-force inches.

Feedback On—When on, the force varies depending on the speed of the affected objects relative to the specified Target Speed. When off, the force remains constant, regardless of the speed of the affected objects.

Reversible—When on, if the object’s speed exceeds the Target Speed setting, the force is reversed. Available only if you turn on Feedback On.

Target Revs—Specifies the maximum revolutions before the feedback takes effect. Speed is specified in units traveled per frame. Available only if you turn on Feedback On.

RPH/RPM/RPS—Specifies the units of measure for Target Revs in revolutions per hour, minute, or second. Available only if you turn on Feedback On.

Gain—Specifies how quickly the force adjusts to approaching the target speed. If set to 100%, the correction is immediate. If set lower, a slower and “looser” response occurs. Available only if you turn on Feedback On.

Note: Setting Gain above 100% can result in over-correction, but is sometimes necessary to overcome damping from other system settings, such as IK damping.
Vortex Space Warp

Periodic Variation group

These settings introduce variations into the force by affecting the Basic Torque value randomly. You can set two waveforms to produce a noise effect.

Enable—Turn on to enable the variations.

Period 1—The time over which the noise variation makes a full cycle. For example, a setting of 20 means one cycle per 20 frames.

Amplitude 1—The strength of the variation (in percent). This option uses the same types of units as the Basic Torque spinner.

Phase 1—Offsets the variation pattern.

Period 2—The next two spinners provide an additional variation pattern to increase the noise.

Amplitude 2—The strength of the variation of the second wave in (percent). This option uses the same types of units as the Basic Torque spinner.

Phase 2—Offsets the variation pattern of the second wave.

Particle Effect Range group

Lets you restrict the Motor effect’s range to a specific spherical volume. This affects particle systems only; it has no effect on dynamics.

Enable—When on, limits the range of the effect to a sphere, displayed as a tri-hooped sphere. The effect falls off increasingly as the particles near the boundary of the sphere.

Range—Specifies the radius of the range of the effect, in units.

Display Icon group

Icon Size—Sets the size of the Motor icon. This is for display purposes only, and does not alter the Motor effect.

Vortex Space Warp

The Vortex space warp applies a force to particle systems (page 2–108), spinning them through a whirling vortex, and then moving them down a long, thin spout or vortex well. Vortex is useful for creating black holes, whirlpools, tornadoes, and other funnel-like objects.

The space warp settings let you control the vortex shape, the well characteristics, and rate and range of particle capture. The shape of the vortex is also affected by particle system settings, such as speed.
Chapter 11: Space Warps and Particle Systems

Particle stream caught in a vortex

Procedure

To create a Vortex space warp:

1. On the Create panel, click Space Warps. Choose Forces from the list, and then click Vortex.

2. Determine which world axis you want the vortex to spiral around, and then drag in the appropriate viewport to create the space warp. For example, if you want the vortex to spin around the vertical world axis, create the space warp in the Top viewport. You can rotate the warp later to change the vortex direction, and animate the warp orientation.

The Vortex warp appears as a curved-arrow icon in the plane you drag in, with a second, perpendicular arrow indicating the axis of rotation as well as the direction of the well. This second axis is called the drop axis.

Note: The position of the space warp plays an important role in the results. The vertical position affects the shape of the vortex, and the horizontal position determines its location.

If you want the particles to spiral around the particle emitter, place both at the same location.

Interface
Timing group

**Time On/Time Off**—The frame numbers at which the space warp becomes active and becomes inactive.

Vortex Shape group

**Taper Length**—Controls the length of the vortex, as well as its shape. Lower settings give you a "tighter" vortex, while higher settings give you a "looser" vortex. Default=100.0.

**Taper Curve**—Controls the shape of the vortex. Low values create a vortex with a wide, flared mouth, while high values create a vortex with nearly vertical sides. Default=1.0. Range=1.0 to 4.0.

Capture and Motion group

This group contains basic settings for Axial Drop, Orbital Speed, and Radial Pull, with Range, Falloff, and Damping modifiers for each.

**Unlimited Range**—When on, Vortex exerts full damping strength over an unlimited range. When off, the Range and Falloff settings take effect.

**Axial Drop**—Specifies how quickly particles move in the direction of the drop axis.

**Range**—The distance from the center of the Vortex icon, in system units, at which Axial Damping has its full effect. Takes effect only when Unlimited Range is turned off.

**Falloff**—Specifies the distance beyond the Axial Range within which Axial Damping is applied. Axial Damping is strongest at the Range distance, decreases linearly out to the limit of the Axial Falloff, and has no effect beyond that. Takes effect only when Unlimited Range is turned off.

**Damping**—Controls the degree to which particle motion parallel to the drop axis is restrained per frame. Default=5.0. Range=0 to 100.

For subtle effects, use values of less than 10%. For more overt effects, try using higher values that increase to 100% over the course of a few frames.

**Orbital Speed**—Specifies how quickly the particles rotate.

**Range**—The distance from the center of the Vortex icon, in system units, at which Orbital Damping has its full effect. Takes effect only when Unlimited Range is turned off.

**Falloff**—Specifies the distance beyond the Orbital Range within which Orbital Damping is applied. Orbital Damping is strongest at the Range distance, decreases linearly out to the limit of the Orbital Falloff, and has no effect beyond that. Takes effect only when Unlimited Range is turned off.

**Damping**—Controls the degree to which orbital particle motion is restrained per frame. Smaller values produce a wide spiral, while larger values produce a thin spiral. Default=5.0. Range=0 to 100.

**Radial Pull**—Specifies the distance from the drop axis at which the particles rotate.

**Range**—The distance from the center of the Vortex icon, in system units, at which Radial Damping has its full effect. Takes effect only when Unlimited Range is turned off.

**Falloff**—Specifies the distance beyond the Radial Range within which Radial Damping is applied. Radial Damping is strongest at the Range distance, decreases linearly out to the limit of the Radial Falloff, and has no effect beyond that. Takes effect only when Unlimited Range is turned off.

**Damping**—Controls the degree to which Radial Pull is restrained per frame. Default=5.0. Range=0 to 100.

**CW/CCW**—Determines whether particles rotate clockwise or counterclockwise.
Display group

Icon Size—Specifies the size of the icon.

---

**Drag Space Warp**

Create panel > Space Warps > Forces > Object Type rollout > Drag

Create menu > Space Warps > Forces > Drag

The Drag space warp is a particle motion damper that reduces particle velocity by a specified amount within a specified range. The damping can be applied linearly, spherically, or cylindrically. Drag is useful for simulating wind resistance, transfers into dense media (like water), impacts with force fields, and other, similar situations.

With each damping type, you can control the damping effect along several vectors. The damping is also affected by particle system settings, such as speed.

Note: To create a more uniform drag effect, default values for all directional parameters are now 5.0%.

**Procedure**

To create a Drag space warp:

1. On the Create panel, click Space Warps. Choose Forces from the list, and then click Drag.

2. Drag in a viewport to create the space warp. The space warp appears initially as a box within a box, indicating that it’s using the default Linear Damping mode.

3. To apply the damping spherically or cylindrically, choose Spherical Damping or Cylindrical Damping in the command panel. Note: The position and orientation of the space warp plays an important role for all three damping types.

4. Change the settings for the current damping type as necessary.

*Drag slows down a stream of particles.*
Interface

Timing group

**Time On/Time Off**—The frame numbers at which the space warp becomes active and becomes inactive.

Damping Characteristics group

This group lets you choose Linear Damping, Spherical Damping, or Cylindrical Damping, plus a set of parameters for each.

**Unlimited Range**—When on, Drag exerts full damping strength over an unlimited range. When off, the Range and Falloff settings for the current damping type take effect.

- **Linear Damping**—Motion for each particle is separated into vectors for the space warp's local X, Y, and Z axes. The area over which damping is exerted for each vector is an infinite plane whose thickness is determined by the corresponding Range setting.
  - **X Axis/Y Axis/Z Axis**—Specifies the percentage of particle motion along the local Drag space warp axis that's affected by the damping.
  - **Range**—Sets the thickness of the "range plane," or the infinite plane perpendicular to the specified axis. Takes effect only when Unlimited Range is turned off.
  - **Falloff**—Specifies the distance beyond the X, Y, or Z Range within which Linear Damping is applied. Damping is strongest at the Range distance, decreases linearly out to the limit of the Falloff, and has no effect beyond that. While Falloff takes effect only beyond the Range, it is measured from the center of the icon, and always has a minimum value equal to the Range value. Takes effect only when Unlimited Range is turned off.

- **Spherical Damping**—When Drag operates in Spherical Damping mode, its icon is a sphere within a sphere. Particle motion is broken up into radial and tangential vectors. Damping...
is applied for each vector within a spherical volume whose radius is set by the Range setting, when Unlimited Range is off.

**Radial/Tangential**—Radial specifies the percentage of particle motion toward or away from the center of the Drag icon that’s affected by the damping. Tangential specifies the percentage of particle motion across the body of the Drag icon that’s affected by the damping.

**Range**—Specifies the distance from the center of the Drag icon, in system units, within which damping is in full effect. Takes effect only when Unlimited Range is turned off.

**Falloff**—Specifies the distance beyond the Radial/Tangential Range within which Linear Damping is applied. Damping is strongest at the Range distance, decreases linearly out to the limit of the Falloff, and has no effect beyond that. While Falloff takes effect only beyond the Range, it is measured from the center of the icon, and always has a minimum value equal to the Range value. Takes effect only when Unlimited Range is turned off.

**Display group**

**Icon Size**—Specifies the size of the icon.

### PBomb Space Warp

Create panel > Space Warps > Forces > Object Type rollout > PBomb

Create menu > Space Warps > Forces > PBomb

The PBomb space warp creates an impulse wave to blow up a particle system, as distinguished from the **Bomb space warp** (page 2–105), which blows up geometry. The PBomb is particularly well suited to the Particle Array (PArray) system with Particle Types set to Object Fragments. This space warp also applies an impulse as a dynamics effect.

The general usage is as follows:

- Create a particle system (recommended: a PArray system (page 2–256) set to Object Fragments).
- Create a PBomb and use **Bind to Space Warp** (page 2–58) to bind it to a non-event-driven particle system. Be sure to bind the PBomb to the particle system and not to the distribution object. Or, if using Particle
Flow, use a Force operator (page 2–204) to apply the space warp to the particle system.

- Adjust the parameters of both the PBomb and the particle system.

2. Create a PArray and use Pick Object to assign the object to blow up as the PArray object-based emitter.

3. In the Basic Parameters rollout > Viewport Display group, choose Mesh to display the fragments as mesh objects in the viewports.

4. On the Particle Generation rollout of PArray, set Speed and Divergence to 0.0. This prevents PArray from moving the particles, letting PBomb do the work.

5. On the Particle Generation rollout, set Life to the length of the active time segment, so that the fragments appear during the entire animation.

6. In the Particle Type rollout > Particle Types group, choose Object Fragments. In the Object Fragment Controls group, choose Number of Chunks, and set the Minimum to about 50, depending on your distribution object and the effect you want.

Now create a particle bomb, and bind it to the particle array.

1. In the Space Warps panel > Particles & Dynamics category, click the PBomb button and drag in a viewport to create the PBomb icon.

2. Use Bind to Space Warp to bind the PArray icon to the PBomb icon. (Don’t bind the distribution object by mistake.)

3. Select the PBomb icon and move to the Modify panel.

4. In the Explosion Parameters group, set Blast Symmetry to Spherical, Start Time to 10, Duration to 1, and Strength to 1.0. Choose Linear, if it’s not already chosen.

5. Drag the time slider between frames 9 and 20 to see the effect.

6. Go to frame 12 and try out various settings. Notice that increasing Strength expands the explosion effect at the current frame. If you
decrease Range enough, the bomb no longer affects all or part of the object (depending on the placement of the PBomb icon). Test the three Blast Symmetry settings by placing the bomb in the center of the object and then seeing the different blast patterns.

Once you get an explosive effect you like, you can return to the PArray settings, add spin or thickness to the fragments, and so on.

### Interface

**Blast Symmetry group**

These options specify the shape, or pattern of the blast effect.

- **Spherical**—The blast force radiates outward from the PBomb icon in all directions. The icon looks like a spherical anarchist’s bomb.

- **Cylindrical**—The blast force radiates outward from and normal to the central axis, or core of the cylindrical icon. The icon looks like a stick of dynamite with a fuse.

- **Planar**—The blast force radiates both up and down, perpendicular to the plane of the planar icon. The icon looks like a plane with arrows pointing up and down along the direction of the blast force.

- **Chaos**—The blast forces vary for each particle or each frame, an effect similar to Brownian motion, with a rate of change in the direction of force equal to the rendering interval rate. Note: This setting is effective only when the Duration spinner is set to 0.

**Explosion Parameters group**

- **Start Time**—The frame number at which the impulse forces are first applied to the particles.

- **Duration**—The number of frames, beyond the first, over which the forces are applied. This value should typically be a small number, such as between 0 and 3.

- **Strength**—The change in velocity along the blast vector, in units per frame. Increasing Strength increases the speed with which the particles are blown away from the bomb icon.

- **Unlimited Range**—The effects of the bomb icon reach all bound particles throughout the scene. This option ignores the Range setting (which specifies the distance of the PBomb effect).

- **Linear**—The impulse forces decay linearly between the full Strength setting to a value of 0 at the specified Range setting.

- **Exponential**—The impulse forces decay exponentially between the full Strength setting to a value of 0 at the specified Range setting.

- **Range**—The maximum distance, in units, over which the PBomb icon affects the bound particle system. If the Range is large enough to reach only...
Path Follow Space Warp

Path Follow Space Warp

Create panel > Space Warps > Forces > Object Type rollout > Path Follow

Create menu > Space Warps > Forces > Path Follow

Path Follow Space Warp

Particles following a spiral path

The Path Follow space warp forces particles to follow a spline path.

Procedures

To create a Path Follow space warp:

1. On the Create panel, click Space Warps. Choose Forces from the list, then on the Object Type rollout, click Path Follow.

2. Click and drag in a viewport to define the size.

The Path Follow warp appears as a box-shaped icon containing curved lines that indicate hypothetical paths.

To set up and use Path Follow:

1. Create a shape consisting of a single spline.
   (You can use shapes with multiple splines, but the software uses only one spline for the path.)

2. Create a particle system and set its parameters to emit particles over a range of frames.

3. On the Create panel, click Path Follow, and drag in a viewport to create the Path Follow icon (a cube with wavy lines). The display and position of this icon don’t affect the particles.

4. On the Basic Parameters rollout, click Pick Shape Object and select the spline you created earlier.

5. Bind the Path Follow icon to the particle system.

6. Adjust the Path Follow parameters to create the particle movement you want.

Note: You can further animate the particle effect by animating the spline vertices.

Tip: To adjust the position of the path or particle system while maintaining access to the Path Follow parameters, turn on Modifier Stack rollout > Pin Stack while the Path Follow space warp is selected.

If the particles don’t follow the emitter after it’s moved, then change any PathFollow parameter, and the motion will be corrected.
Current Path group

Lets you choose the path for the particles, and specify the range of influence of the Space Warp.

Object—Displays the name of the currently assigned path.

Pick Shape Object—Click this, and then click a shape in the scene to select it as a path. You can use any shape object as a path; if you select a multiple-spline shape, only one the lowest-number spline is used. You can also use NURBS curves as paths.

Unlimited Range—When off, the range of influence of the space warp is limited to the value set in the Distance spinner. When on, the space warp influences all bound particles in the scene, regardless of their distance from the path object.

Range—Specifies the range of influence when Unlimited Range is off. This is the distance between the path object and the particle system. The position of the Path Follow space warp's icon is ignored.

Motion Timing group

These controls affect how long particles are influenced by Path Follow.

Start Frame—The frame at which Path Follow begins to influence the particles.

Travel Time—The time each particle takes to traverse the path.

Variation—The amount by which each particle's travel time can vary.

Last Frame—The frame at which Path Follow releases the particles and no longer influences them.

Particle Motion group

The controls in this area determine the motion of particles.
Gravity Space Warp

**Along Offset Splines**—The distance between the particle system and the path alters the effect of the particle motion. If the first vertex of the spline is at the birthplace of the particle, the particle follows the spline path. If you move the path away from the particle system, the particles are affected by the offset.

**Along Parallel Splines**—Particles follow a copy of the selected path, parallel to the particle system. In this mode, the position of the path relative to the particle system does not matter. The orientation of the path, however, affects the particle stream.

**Constant Speed**—When on, all particles travel at the same speed.

**Stream Taper**—Causes particles to converge or diverge toward the path over time, or to simultaneously converge and diverge. You specify the effect by choosing Converge, Diverge, or Both (see following). This provides a tapering effect over the length of the path.

**Variation**—The amount by which Stream Taper can vary for each particle.

**Converge**—When Stream Taper is greater than 0, the particles move in toward the path as they follow the path. The effect is that the stream tapers from larger to smaller over time.

**Diverge**—Provides the opposite effect of Converge. The particles diverge from the path over time.

**Both**—Splits the particle stream, causing some particles to converge and others to diverge.

**Stream Swirl**—Specifies the number of turns by which particles spiral about the path. In conjunction with Stream Taper, alters the diameter of the spiral.

Stream Swirl is generally more effective when you choose Along Offset Splines.

**Variation**—The amount by which each particle can vary from the Spiral value.

**Clockwise**—Particles spiral in a clockwise direction.

**Counterclockwise**—Particles spiral in a counterclockwise direction.

**Bidirectional**—The stream is split so that particles spiral in both directions.

**Uniqueness group**

Provides a seed number for unique generation of the particle pattern.

**Seed**—Specifies the seed number for the current Path Follow.

**Display Icon group**

Affects the display of the Path Follow icon.

**Icon Size**—Specifies the size of the Path Follow icon. Does not alter the Path Follow effect.

---

**Gravity Space Warp**

Create panel > Space Warps > Forces > Object Type rollout > Gravity

Create menu > Space Warps > Forces > Gravity

Particles falling because of gravity

The Gravity space warp simulates the effect of natural gravity on particles generated by a particle system. Gravity is directional. Particles moving in the direction of the gravity arrow accelerate. Particles moving against the arrow decelerate. In the case of spherical gravity, motion is toward the icon. Gravity can also be used as an effect in dynamics simulations. See *Dynamics Utility (page 2–686).*
Gravity effect on snow

Procedure

To create gravity:

1. On the Create panel, click Space Warps. Choose Forces from the list, then on the Object Type rollout, click Gravity.

2. Drag in a viewport.

   The Gravity icon appears. For planar gravity (the default), the icon is a wireframe square with a direction arrow on one side. For spherical gravity, the icon is a wireframe sphere.

   The initial direction of planar gravity is along the negative Z axis of the construction grid that is active in the viewport where you drag. You can rotate the gravity object to change the direction.

Interface

Force group

**Strength**—Increasing Strength increases the effect of gravity; that is, how objects move in relation to the Gravity icon’s direction arrow. Strength less than 0.0 creates negative gravity, which repels particles moving in the same direction and attracts particles moving in the opposite direction. When Strength is set to 0.0, the Gravity space warp has no effect.

**Decay**—When Decay is set to 0.0, the Gravity space warp has the same strength throughout world space. Increasing the Decay value causes gravity strength to diminish as distance increases from the position of the gravity warp object. Default=0.0.

**Planar**—Gravity effect is perpendicular to the plane of the Gravity warp object throughout the scene.

**Spherical**—Gravity effect is spherical, centered on the Gravity warp object. This choice is effective for creating water fountain or planetary effects.

Display group

**Range Indicators**—When on, and when the Decay value is greater than 0.0, icons in the viewports indicate the range at which the force of gravity is half the maximum value. For the Planar option, the indicators are two planes; for use the Spherical option, the indicator is a double-hooped sphere.

**Icon Size**—Size of the Gravity warp object icon, in active units. You set the initial size when you drag to create the Gravity object. This value does not change the gravity effect.
Wind Space Warp

Create panel > Space Warps > Forces > Object Type rollout > Wind
Create menu > Space Warps > Forces > Wind

Wind changing the direction of the spray of a fountain

The Wind space warp simulates the effect of wind blowing particles generated by a particle system. Wind is directional. Particles moving in the direction of the wind arrow accelerate. Particles moving against the arrow decelerate. In the case of spherical wind, motion is toward or away from the icon. Wind is similar in effect to the Gravity space warp, but has added parameters for turbulence and other features characteristic of wind in the natural world. Wind can also be used as an effect in dynamics simulations. See Dynamics Utility (page 2–686).

Procedure

To create wind:

1. On the Create panel, click Space Warps. Choose Forces from the list, then on the Object Type rollout, click Wind.
2. Drag in a viewport.

The wind icon appears. For planar wind (the default), the icon is a wireframe square with a direction arrow coming out of one side. For spherical wind, the icon is a wireframe sphere. The initial direction of planar wind is along the negative Z axis of the construction grid that is active in the viewport where you drag. You can rotate the wind object to change the direction.

Force group

These settings are comparable to the Gravity parameters.

**Strength**—Increasing Strength increases the wind effect. Strength less than 0.0 creates a suction. It
repels particles moving in the same direction and attracts particles moving in the opposite direction. When Strength is 0.0, the Wind warp has no effect.

**Decay**—When Decay is set to 0.0, the Wind warp has the same strength throughout world space. Increasing the Decay value causes wind strength to diminish as distance increases from the position of the Wind warp object. Default=0.0.

**Planar**—Wind effect is perpendicular to the plane of the Wind warp object, throughout the scene.

**Spherical**—Wind effect is spherical, centered on the Wind warp object.

**Wind group**

These settings are specific to the Wind space warp.

**Turbulence**—Causes particles to change course randomly as the wind blows them. The greater the value, the greater the turbulence effect.

**Frequency**—When set greater than 0.0, causes turbulence to vary periodically over time. This subtle effect is probably not visible unless your bound particle system generates a large number of particles.

**Scale**—Scales the turbulence effect. When Scale is small, turbulence is smoother and more regular. As Scale increases, turbulence grows more irregular and wild.

**Display group**

**Range Indicators**—When the Decay value is greater than zero, icons appear in the viewports that represent the range at which the force of wind is half the maximum value. When you use the Planar option, the indicators are two planes; when you use the Spherical option, the indicator is a double-hooped sphere.

**Icon Size**—Size of the Wind warp object icon, in active units. You set the initial Icon Size value when you drag to create the wind object. This value does not change the wind effect.

---

**Displace Space Warp**

Create panel > Space Warps > Geometric/Deformable > Object Type rollout > Displace

Create menu > Space Warps > Geometric/Deformable > Displace

![Displace used to change the surface in the container](image)

The Displace space warp acts as a force field to push and reshape an object’s geometry. Displace affects both geometry (deformable objects) and particle systems. There are two basic ways to use the Displace space warp:

- Apply the gray scale of a bitmap to generate the displacement amount. Black areas of the 2D image are not displaced. Whiter areas push outward, causing a 3D displacement of geometry.
- Apply displacement directly by setting displacement Strength and Decay values.

The Displace space warp works similarly to the Displace modifier, except that, like all space warps, it affects world space rather than object space. Use the Displace modifier when you need to create detailed displacement of a small number of objects. Use the Displace space warp to displace...
particle systems, a large number of geometric objects at once, or an object relative to its position in world space.

For geometry, the detail of the displacement depends on the number of vertices. Use the Tessellate modifier to tessellate faces you want to show in greater detail.

Procedures

To create a Displace space warp:

1. On the Create panel, click Space Warps. Choose Geometric/Deformable from the list, and then on the Object Type rollout, click Displace.

2. Drag in a viewport to create the Displace warp object, which appears as a wireframe. Its shape depends on the active mapping parameter settings. Regardless of the mapping, a single drag creates the space warp.

3. Bind the space warp to an appropriate object.

To assign a bitmap to a displace space warp:

1. Select the Displace warp object.

2. In the Parameters rollout > Displacement group, click the Bitmap button (labeled "None" by default). Use the selection dialog to choose a bitmap.

3. Set the Strength value. Vary the strength of the field to see how the bitmap displaces the object’s geometry.

Interface

Displacement group

These are the basic controls for Displace space warps.

Strength—When set to 0.0, the Displace warp has no effect. Values greater than 0.0 displace object geometry or particles away from the position of
Chapter 11: Space Warps and Particle Systems

the Displace space warp object. Values less than 0.0 displace geometry toward the warp. Default=0.0

Decay—By default, the Displace warp has the same strength throughout world space. Increasing Decay causes displacement strength to diminish as distance increases from the position of the Displace warp object. Default=0.0

Luminance Center—By default, the Displace space warp centers the luminance by using medium (50%) gray as the zero displacement value. Gray values greater than 128 displace in the outward direction (away from the Displace warp object) and gray values less than 128 displace in the inward direction (toward the Displace warp object). You can adjust the default using the Center spinner. With a Planar projection, the displaced geometry is repositioned above or below the Planar gizmo. Default=0.5. Range=0 to 1.0.

Image group
These options let you choose a bitmap and map to use for displacement.

Bitmap—(Labeled “None” by default.) Click to assign a bitmap or map from a selection dialog. After you choose a bitmap or map, this button displays the bitmap’s name.

Remove Bitmap—Click to remove the bitmap or map assignment.

Blur—Increase this value to blur or soften the effect of the bitmapped displacement.

Map group
This area contains mapping parameters for a bitmapped Displace warp. The mapping options are comparable to those options used with mapped materials. The four mapping modes control how the Displace warp object projects its displacement. The warp object’s orientation controls where in the scene the displacement effect will appear on bound objects.

Planar—Projects the map from a single plane.

Cylindrical—Projects the map as if it were wrapped around the cylinder.

Spherical—Projects the map from a sphere, with singularities at the top and bottom of the sphere, where the bitmap edges meet at the sphere’s poles.

Shrink Wrap—Truncates the corners of the map and joins them all at a single pole, creating one singularity.

Length, Width, Height—Specify the dimensions of the bounding box of the space warp gizmo. Height has no effect on planar mapping.

U/V/W Tile—The number of times the bitmap repeats along the specified dimension. The default value of 1.0 maps the bitmap once; a value of 2.0 maps the bitmap twice, and so on. Fractional values map a fractional portion of the bitmap in addition to copies of the whole map. For example, a value of 2.5 maps the bitmap two and one-half times.

Flip—Reverses the orientation of the map along the corresponding U, V, or W axis.

Deflectors

POmniFlect Space Warp

POmniFlect is a planar version of the omniflector type of space warp. It provides enhanced functionality over that found in the original Deflector space warp, including refraction and spawning capabilities.
POmniFlect viewport icon

**Procedure**

To create a POmniFlect space warp:

1. On the Create panel, click Space Warps. Choose Deflectors from the list, then on the Object Type rollout, click POmniFlect.

2. Drag in a viewport to create the planar icon.
   
   Note: Because particles bounce off the icon, the size of the icon affects particle deflection.

3. Apply the deflector to the particle system using the appropriate method:
   
   - If using *Particle Flow* (page 2–109), specify the deflector in the *Collision test* (page 2–212) or *Collision Spawn test* (page 2–215) parameters.
   
   - If using a *non-event-driven particle system* (page 2–237), bind (page 2–58) the particle system to the deflector icon.

4. Position the POmniFlect icon to interrupt the particle stream.

5. Adjust the POmniFlect parameters as necessary.

Timing group

The two spinners specify the start frame and end frame of the deflection effect.

**Time On/Off**—Time On specifies the frame at which the deflection begins, and Time Off specifies the frame at which the deflection ends.

Reflection group

These options affect the *reflection* of particles from the space warp. The POmniFlect can reflect or refract particles, or perform a combination of the two.

**Reflects**—Specifies the percentage of particles to be reflected by the POmniFlect. See also Refracts, later in this topic, for methods of combining the two effects.

**Bounce**—This is a multiplier that specifies how much of the initial speed of the particle is maintained after collision with the POmniFlect. Using the default setting of 1.0 causes the particle to rebound with the same speed as it collides. A real-world effect would usually be less than 1.0. For a “rubber” effect, set greater than 1.0.

**Variation**—Specifies the variation of Bounce applied to the range of particles. For example, a Variation of 50% applied to a Bounce setting of 1.0 would result in randomly applied Bounce values ranging from 0.5 to 1.5.

**Chaos**—Applies a random variation to the bounce angle. When set to 0.0 (no chaos), all particles bounce off the POmniFlect surface perfectly (like banking pool balls). A non-zero setting causes the deflected particles to scatter.

Refraction group

These settings are similar to those in the Reflection group, but these affect the *refraction* of particles as they pass through the POmniFlect, causing the direction of the particles to change.

**Refracts**—Specifies the percentage of particles not already reflected that will be refracted by the POmniFlect.

Note: The Refracts value affects only those particles not already reflected because the reflected particles are processed before the refracted particles. Thus, if you set Reflects to 50% and Refracts to 50%, you would not get a 50/50 split of particles. Rather, half the particles would be reflected, and then *half the remainder* (25% of the total) would be refracted. The remaining particles either pass through without being refracted or are passed on to Spawn Effects.

To get a 50/50 split of reflection and refraction, set Reflects to 50% and Refracts to 100%.

**Pass Vel**—Specifies how much of a particle’s initial speed is maintained after passing through the POmniFlect. The default setting of 1 retains the initial speed is retained, so there’s no change. A setting of 0.5 reduces the speed by half.

**Variation**—Specifies the variation of Pass Velocity applied to the range of particles.

**Distortion**—Controls the angle of refraction. A value of 0 means there’s no refraction. A value of 100% sets the angle of the particles to be parallel with the POmniFlect surface. A value of –100% sets the angle perpendicular to the surface. The Distortion effect is reversed when particles strike the POmniFlect from the back side.

Note: Distortion and Refraction do not work properly when particles strike the POmniFlect surface at exactly 90 degrees. In this case, any positive Distortion settings cause a scattering of particles, while negative values have no effect.

**Variation**—Specifies a range of variation of the Distortion effect.

**Diffusion**—Applies a diffusion effect to the refraction by randomly modifying each particle’s
Distortion angle by the Diffusion angle. This effectively scatters the particles into a hollow cone.

**Variation**—Specifies a range of variation of the Diffusion value.

**Common group**

**Friction**—The amount by which particles are slowed as they move along the deflector surface. A value of 0% means they're not slowed at all. A value of 50% means they're slowed to half their original speed. A value of 100% means they stop moving when they strike the surface. Default=0%. Range=0% to 100%.

Tip: To have particles slide along a deflector surface, set Bounce to 0. Also, unless influenced by a force such as Wind or Gravity, particles meant to slide should strike the surface at an angle other than 90 degrees.

**Inherit Vel**—(Velocity Inheritance) Determines how much of a moving POmniFlect's speed is applied to reflected or refracted particles. For example, if Inherit Vel is 1.0, particles with no motion that are hit by a moving PomniFlect inherit the speed of the POmniFlect at the point of collision.

**Spawn Effects Only group**

These settings affect only particles set to Spawn On Collision that do not either reflect or refract from the omniflector. See Particle Spawn Rollout (page 2–271). The Spawns percentage spinner works like the Reflects and Refracts percentage spinners, but is the third in line to be processed. Thus, if either Reflects or Refracts are set to 100%, no particles are affected by these settings. Note also that reflective or refractive particles spawn upon collision, regardless of the settings in this group.

**Spawns**—Specifies the percentage of particles that can use spawn effects.

**Pass Vel**—Specifies how much of the particle's initial speed is maintained after passing through the POmniFlect.

**Variation**—Specifies the variation of the Pass Velocity setting applied to the range of particles.

**Display Icon group**

**Width/Height**—Specify the width and height of the POmniFlect icon. This is for display purposes only and does not influence the deflector effect.

**PDynaFlect Space Warp**

PDynaFlect (planar dynamics deflector) is a planar version of the dynaflector, a special class of space warp that lets particles affect objects in a dynamics situation. For example, if you want a stream of particles to strike an object and knock it over, like the stream from a firehose striking a stack of boxes, use a dynaflector.

Note: You use dynaflectors in the same way as omniflectors; that is, you can use them as deflectors alone, with no dynamics simulation. Because they take physics into account, dynaflectors are slower than omniflectors. Therefore, it is recommended that you use dynaflectors only when a dynamics simulation is involved.
Chapter 11: Space Warps and Particle Systems

**Procedure**

Many dynaflector parameters are the same as those for omniflectors. However, the procedure of associating the dynaflector with both the particle system and the object to be affected is more complex than the simple binding used by omniflector.

**To create a particle/dynamics system:**

1. Create or load a scene containing a *non-event-driven particle system (page 2–237)* and an object to be affected by the particles (hereafter called "the object"). Position and orient the two as desired so that the particles strike the object.
   - The icon for the particle system must be visible in at least one non-disabled viewport.
   - On the Basic Parameters rollout of the particle system, set Percentage of Particles to 100%. Otherwise, only those particles displayed in the viewport will be calculated.

2. On the Create panel, click Space Warps. Choose Deflectors from the drop-down list, and then click one of the dynaflector buttons (PDynaFlect, SDynaFlect, or UDynaFlect). Drag in a viewport to create the deflector.

3. Do either of the following:
   - If using a PDynaFlect or SDynaFlect, position the space warp icon where the particles strike (or will strike) the object. Resize and orient it as needed.
   - If using a UDynaFlect, go to the Modify panel > Parameters rollout, click the Pick Object button, and then select the object. The position of the space warp icon doesn't matter, and it's not necessary to link the two.

4. Bind the particle system to the dynaflector using the toolbar *Bind to Space Warp button (page 2–58)*.

5. Go to the Utilities panel and open the Dynamics utility.

6. On the Dynamics rollout, click New to create a new simulation.

7. Click Edit Object List, and add the object to the dynamics simulation.

8. Click Edit Object. On the Edit Object dialog, click Assign Object Effects and assign the dynaflector to the object. Note: Because only those particles displayed in viewports are used in the dynaflector calculations, solving the dynamics involves three requirements:

9. On the Dynamics rollout, turn on the Update Display w/Solve check box above the Solve button.

10. Solve the simulation.

Timing group

The two spinners specify the start frame and end frame of the deflection effect.

**Time On/Off**—Time On specifies the frame at which the deflection begins, and Time Off specifies the frame at which the deflection ends.

Particle Bounce group

These settings affect the reflection of particles from the space warp.

**Reflects**—Specifies the percentage of particles to be reflected by the PDynaFlect. This affects both the particles and the dynamics reaction of the object struck by the particles. The more particles that strike the affected object, the more force applied to that object. If set to 0.0, the particles have no effect on the object.

**Bounce**—This is a multiplier that specifies how much of the initial speed of the particle is maintained after collision with the PDynaFlect. Using the default setting of 1.0 causes the particle to rebound with the same speed as it collides. A real-world effect would usually be less than 1.0. For a "flubber" effect, set greater than 1.0.

**Variation**—Specifies the variation of Bounce applied to the range of particles. For example, a Variation setting of 50% applied to a Bounce setting of 1.0 would result in randomly applied Bounce values ranging from 0.5 to 1.5.

**Chaos**—Applies a random variation to the bounce angle. When you set Chaos to 0.0 (no chaos), all particles bounce off the PDynaFlect surface perfectly (like banking pool balls). A non-zero setting causes the deflected particles to scatter.

**Friction**—The amount by which particles are slowed as they move along the deflector surface. A value of 0% means they’re not slowed at all. A value of 50% means they’re slowed to half their original speed. A value of 100% means they stop moving when they strike the surface. Default=0%. Range=0% to 100%.

Tip: To have particles slide along a deflector surface, set Bounce to 0. Also, unless influenced by a force such as Wind or Gravity, particles meant to slide should strike the surface at an angle other than 90 degrees.

**Inherit Vel**—(Velocity Inheritance) Determines how much of a moving PDynaFlect’s speed is applied to reflected or refracted particles.
For example, if Inherit Vel is 1.0, particles with no motion that are hit by a moving PDynaFlect inherit the speed of the PDynaFlect at the point of collision.

**Physical Properties group**

These options let you set the mass of each particle.

**Mass**—Specifies the mass based on the chosen unit.

- **gram**—One gram equals 1/1000 kg or 22/1000 Lbm at a gravity of 1.0.
- **Kg**—One kg (kilogram) equals 1000 grams or 2.2 Lbm at a gravity of 1.0.
- **Lbm**—One Lbm (pounds-mass) equals 5/11 kg or 454 5/11 grams at a gravity of 1.0. (Pounds-mass, the amount of mass in one pound of weight, is dependent on gravity. For pounds-mass values at a gravity other than 1.0, multiply the pounds-mass value by the gravity factor.)

**Display Icon group**

**Width/Height**—Specify the width and height of the PDynaFlect icon. This is for display purposes only and does not influence the deflector effect.

---

**SOmniFlect Space Warp**

SOmniFlect is the spherical version of the omniflector type of space warp. It provides more options than the original SDeflector. Most settings are the same as those in POmniFlect (page 2–78). The difference is that this space warp provides a spherical deflection surface rather than the planar surface. The only settings that are different are in the Display Icon area, in which you set the Radius, instead of the Width and Height.

Note: Opposite sides of the deflectors reverse the distortion effect. Thus, a refracted particle passing through the SOmniFlect hits its outside surface first, and then its inside surface. A positive Distortion value warps the particles toward the perpendicular; then, as the particles pass through the inside surface, the same positive Distortion value warps them toward the parallel.

---

**Procedure**

**To create an SOmniFlect space warp:**

1. **On the Create panel, click Space Warps. Choose Deflectors from the list, then on the Object Type rollout, click SOmniFlect.**
2. Drag in a viewport to create the spherical icon. Note: Because particles bounce off the icon, the size of the icon affects particle deflection.
3. **Apply the deflector to the particle system using the appropriate method:**
   - If using Particle Flow (page 2–109), specify the deflector in the Collision test (page 2–212) or Collision Spawn test (page 2–215) parameters.
   - If using a non-event-driven particle system (page 2–237), bind (page 2–58) the particle system to the deflector icon.
4. **Position the SOmniFlect icon to interrupt the particle stream.**
5. Adjust the SOmniFlect parameters as necessary.

**SDynaFlect Space Warp**

Create panel > Space Warps > Deflectors > Object Type rollout > SDynaFlect

The SDynaFlect space warp is a spherical dynamics deflector. It's like the PDynaFlect (page 2–81) warp, except that it's spherical, and its Display Icon spinner specifies the icon's Radius value.

**UOmniFlect Space Warp**

Create panel > Space Warps > Deflectors > Object Type rollout > UOmniFlect

UOmniFlect, the universal omniflector, provides more options than the original UDeflector. This space warp lets you use any other geometric object as a particle deflector. The deflections are face accurate, so the geometry can be static, animated, or even morphing or otherwise deforming over time.

Note: Some particle “leakage” can occur with this deflector, particularly when you use many particles and a complex deflector object. To avoid this, perform a test render to check for leaking particles, and then add POmniFlects to catch the strays.

**Procedure**

To use the UOmniFlect space warp:

To use a universal omniflector, you need a minimum of three objects in the scene:

- The particle system
- The UOmniFlect space warp
- The object used as the deflector

1. Add or select an object used as the deflector.

2. Create a particle system whose particles intersect the deflector object.

3. On the Create panel, click Space Warps. Choose Deflectors from the list, and then click UOmniFlect.

4. Click and drag in a viewport to place the space warp icon.

Note: The size and position of the UOmniFlect icon do not alter the effect.

5. Apply the deflector to the particle system using the appropriate method:

   - If using Particle Flow (page 2–109), specify the deflector in the Collision test (page 2–212) or Collision Spawn test (page 2–215) parameters.
Chapter 11: Space Warps and Particle Systems

If using a non-event-driven particle system (page 2-237), bind (page 2-58) the particle system to the deflector icon.

6. On the Modify panel > Parameters rollout > Object-Based OmniFlector group, click Pick Object, and then select the object to use as a deflector.

7. Adjust the particle system and UOmniFlect parameters as necessary.

**Interface**

**Parameters rollout**

The settings for the UOmniFlect are the same as those for POmniFlect (page 2-78), with the following additions:

**Object-Based OmniFlector group**

- **Item**—Displays the name of the selected object.
- **Pick Object**—Click this, and then select any renderable object to use as a deflector.

**Display Icon group**

- **Icon Size**—Specifies the size of one side of the square UOmniFlect icon.

**UDynaFlect Space Warp**

The UDynaFlect space warp is a universal dynamics deflector that lets you use the surface of any object as both the particles deflector and the surface that reacts dynamically to the particle impact.

The procedures and options for using UDynaFlect are the same as for PDynaFlect (page 2-81), with the following changes and additions.

Note: When you use UDynaFlect, you must indicate the object to be affected with the Pick Object button. Linking is not necessary.
Interface

Object-Based DynaFlector group

Item—Displays the name of the selected object.

Pick Object—Click this, and then select any renderable object to use as a deflector.

Display Icon group

Icon Size—Specifies the size of the UDynaFlect icon.

SDeflector Space Warp

Create menu > Space Warps > Deflectors > SDeflector

The SDeflector space warp serves as a spherical deflector of particles.

Object-Based DynaFlector allows you to choose the object to use as a deflector.

Item—Displays the name of the selected object.

Pick Object—Click this, and then select any renderable object to use as a deflector.

Display Icon group

Icon Size—Specifies the size of the UDynaFlect icon.

Procedure

To create an SDeflector:

1. On the Create panel, click Space Warps. Choose Deflectors from the list, then on the Object Type rollout, click SDeflector.
2. Drag in a viewport to create the spherical icon.
Chapter 11: Space Wars and Particle Systems

Note: Because particles bounce off the perimeter of the spherical icon, the size of the icon affects particle deflection.

3. Apply the deflector to the particle system using the appropriate method:
   - If using Particle Flow (page 2–109), specify the deflector in the Collision test (page 2–212) or Collision Spawn test (page 2–215) parameters.
   - If using a non-event-driven particle system (page 2–237), bind (page 2–58) the particle system to the deflector icon.

4. Position the SDeflector icon to interrupt the particle stream.
5. Adjust the SDeflector parameters as necessary.

Interface

Particle Bounce group
These settings determine how the deflector affects the bound particles.

**Bounce**—Determines the speed with which particles bounce off the deflector. At 1.0, the particles bounce at the same speed as they approach. At 0, they don’t deflect at all.

**Variation**—The amount by which each particle can vary from the Bounce setting.

**Chaos**—The amount of variation from the perfect angle of reflection (found when Chaos is set to 0.0). 100% induces a variation in reflection angle of up to 90 degrees.

**Friction**—The amount by which particles are slowed as they move along the deflector surface. A value of 0% means they’re not slowed at all. A value of 50% means they’re slowed to half their original speed. A value of 100% means they stop moving when they strike the surface. Default=0%. Range=0% to 100%.

Tip: To have particles slide along a deflector surface, set Bounce to 0. Also, unless influenced by a force such as Wind or Gravity, particles meant to slide should strike the surface at an angle other than 90 degrees.

**Inherit Vel**—(Velocity Inheritance) When the value is greater than 0, the motion of the deflector affects particles as well as the other settings. For example, to animate the SDeflector passing through a passive array of particles, turn up this value to affect the particles.

Display Icon group
This option affects the display of the icon.

**Diameter**—Specifies the diameter of the SDeflector icon. This setting also alters the effect of the deflection, because particles bounce off the perimeter of the icon. The scale of the icon also affects the particles.
**UDeflector Space Warp**

Create panel > Space Warps > Deflectors > Object Type rollout > UDeflector

Create menu > Space Warps > Deflectors > UDeflector

Particles scatter when they strike a UDeflector object

The UDeflector is a universal deflector that lets you use any object as a particle deflector.

**Procedure**

**To create a UDeflector:**

1. On the Create panel, click Space Warps. Choose Deflectors from the list, then on the Object Type rollout, click UDeflector.

2. In a viewport, drag out a rectangle to add a UDeflector warp to the scene.

3. On the command panel, click the Pick Object button and select an object to be a particle deflector.

4. Apply the deflector to the particle system using the appropriate method:
   - If using *Particle Flow* (page 2–109), specify the deflector in the *Collision test* (page 2–212) or *Collision Spawn test* (page 2–215) parameters.
   - If using a *non-event-driven particle system* (page 2–237), *bind* (page 2–58) the particle system to the deflector icon.

5. Position the UDeflector icon to interrupt the particle stream.

6. Adjust the UDeflector parameters as necessary.

**Interface**

**Object-Based Deflector group**

*Item*—Displays the name of the selected object.

*Pick Object*—Click this, and then click any renderable mesh object to be used as a deflector.

**Particle Bounce group**

*Bounce*—Determines the speed with which particles bounce off the deflector. At 1.0, the particles bounce at the same speed as they approach. At 0, they don’t deflect at all.
Variation—The amount by which each particle can vary from the Bounce setting.

Chaos—The amount of variation from the perfect angle of reflection (found when Chaos is set to 0.0). 100% induces a variation in reflection angle of up to 90 degrees.

Friction—The amount by which particles are slowed as they move along the deflector surface. A value of 0% means they’re not slowed at all. A value of 50% means they’re slowed to half their original speed. A value of 100% means they stop moving when they strike the surface. Default=0%. Range=0% to 100%.

Tip: To have particles slide along a deflector surface, set Bounce to 0. Also, unless influenced by a force such as Wind or Gravity, particles meant to slide should strike the surface at an angle other than 90 degrees.

Inherit Vel—(Velocity Inheritance) When greater than 0, the motion of the deflector affects particles as well as the other settings. For example, to animate the SDeflector passing through a passive array of particles, turn up this value to affect the particles.

Display Icon group

Icon Size—This spinner displays and lets you change the size of the icon.

Deflector Space Warp

Create panel > Space Warps > Deflectors > Object Type rollout > Deflector

Create menu > Space Warps > Deflectors > Deflector

Two streams of particles striking two deflectors

The Deflector space warp acts as a planar shield to repel the particles generated by a particle system. For example, you can use Deflector to simulate pavement being struck by rain. You can combine a Deflector space warp with a Gravity space warp to produce waterfall and fountain effects.

See also
SDeflector Space Warp (page 2–87)
UDeflector Space Warp (page 2–89)

Procedure

To create a deflector:

1. On the Create panel, click Space Warps. Choose Deflectors from the list, then on the Object Type rollout, click Deflector.

2. Drag in a viewport to define the deflection area. The deflector appears as a wireframe rectangle.

3. Apply the deflector to the particle system using the appropriate method:
• If using Particle Flow (page 2–109), specify the deflector in the Collision test (page 2–212) or Collision Spawn test (page 2–215) parameters.

• If using a non-event-driven particle system (page 2–237), bind (page 2–58) the particle system to the deflector icon.

**Interface**

<td>0.0</td>
</tr>
</tbody>
</table>

The deflector’s effect is controlled mainly by its size and orientation in the scene, relative to the particle system that is bound to it. You can also adjust how strongly the deflector deflects particles.

**Bounce**—Controls the speed at which particles bounce off the deflector. At a setting of 1.0, particles bounce off the deflector at the same speed they struck it. At 0.0, particles do not bounce at all. At values between 0.0 and 1.0, particles bounce off the deflector at a speed reduced from their initial speed. At values greater than 1.0, particles bounce off the deflector at a speed greater than their initial speed. Default=1.0.

**Variation**—The amount by which each particle can vary from the Bounce setting.

**Chaos**—The amount of variation from the perfect angle of reflection (found when Chaos is set to 0.0). 100% induces a variation in reflection angle of up to 90 degrees.

**Friction**—The amount by which particles are slowed as they move along the deflector surface. A value of 0% means they’re not slowed at all. A value of 50% means they’re slowed to half their original speed. A value of 100% means they stop moving when they strike the surface. Default=0%. Range=0% to 100%.

Tip: To have particles slide along a deflector surface, set Bounce to 0. Also, unless influenced by a force such as Wind or Gravity, particles meant to slide should strike the surface at an angle other than 90 degrees.

**Inherit Vel**—(Velocity Inheritance) When the value is greater than 0, the motion of the deflector affects particles as well as the other settings. For example, if you want an animated SDeflector passing through an array of particles to affect the particles, turn up this value.

**Width**—Sets the deflector’s width.

**Length**—Sets the deflector’s length.

---

**Geometric/Deformable**

**FFD(Box) Space Warp**

Create panel > Space Warps > Geometric/Deformable > Object Type rollout > FFD(Box)

Create menu > Space Warps > Geometric/Deformable > FFD(Box)

Free-form deformations (FFDs) provide a method of deforming an object by adjusting the control points of a lattice. The offset position of the control points to the original lattice source volume causes the distortion of the affected object.
The FFD(Box) space warp is a box-shaped lattice FFD object similar to the original FFD modifiers. This FFD is available as both an object modifier and a space warp. For information on the object-modifier version, see *FFD (Box/Cylinder) Modifiers* (page 1–685).

You create FFD space warps as separate objects similarly to the way you create standard primitives: by dragging the mouse in the viewport. The result is a lattice of control points. The source lattice of an FFD modifier is fitted to the geometry it’s assigned to in the stack. This might be a whole object or a sub-object selection of faces or vertices.

Because FFD space warps are separate objects, they carry their own adjustable dimension parameters among the creation parameters.

You can apply object modifiers to space warp objects. For example, you can use the Linked XForm modifier with a space-warp FFD.
4. Determine the relative placement of the lattice to the object.
   If the lattice is to be outside of the object, turn on All Vertices. To affect only those vertices inside the lattice, choose Only In Volume, and position the lattice accordingly.

5. In the modifier stack display, choose Control Points as the sub-object level for FFD(box).

6. Adjust the control points.
   Note: The distortion effect of an FFD modifier is based on the positional offset of the control points from their original positions in the source volume. If you don't move control points, there is no effect on the target object. Keep this in mind when using space-warp version of the FFD.

If you're using the Deform group > All Vertices option, once you've distorted the object you can set the Falloff value to adjust how much the lattice affects the object, based on distance. This is particularly useful if the lattice is animated to approach or move away from the target object. When Falloff is set to 0, all the vertices are affected, regardless of distance.

Note: When you're at the base-parameters level of an FFD modifier in the Stack, the Show End Result button is turned off and spring-loaded, as it is in an Edit Mesh modifier.

Moving control points in the lattice deforms the object.

Procedure

To use the FFD(box) space warp:

1. On the Create panel, click Space Warps. Choose Geometric/Deformable from the list, then on the Object Type rollout, click FFD(Box).

2. Drag in a viewport to create the base. Release the mouse button, and then move the mouse to define the height of the FFD lattice. Click to finish the lattice.

3. Bind the lattice to the object you want to deform.
This rollout lets you set the size and resolution of the lattice, and how it displays and deforms.

Dimensions group
These options let you adjust the unit dimensions of the source volume, and specify the number of control points in the lattice. Note that the point dimensions are displayed beside the modifier name in the Stack list.

Length, Width, Height—These three spinners display and let you adjust the length, width, and height of the lattice. To create the space warp, you drag the mouse in the same way that you would to create a standard Box primitive. Note that these spinners don’t exist in the object-modifier version of the FFD.

Label—Displays the current number of controls points in the lattice (for example: 4x4x4).

Set Number of Points—Displays a dialog containing three spinners labeled Length, Width, and Height, plus OK/Cancel buttons. Specify the number of control points you want in the lattice, and then click OK to make the change.

Note: Make changes to the dimensions before you adjust the positions of the lattice control points. When you change the number of control points with this dialog, any adjustments you’ve already made to the control points are lost; however, you can undo this use of the dialog.

Display group
These options affect the display of the FFD in the viewports.

Lattice—When turned on, lines are drawn connecting the control points to make a grid. Although viewports can become cluttered when these extra lines are drawn, they help to visualize the lattice.

Source Volume—When on, the control points and lattice are displayed in their unmodified state. This display is helpful when you’re adjusting the source volume to affect specific vertices that lie within or without it. See the All Vertices and Only in Volume options, later in this topic.

Deform group
These options provide controls that specify which vertices are affected by the FFD.
Only In Volume—Only vertices that lie inside the source volume are deformed. Vertices outside the source volume are not affected.

All Vertices—All vertices are deformed regardless of whether they lie inside or outside the source volume, depending on the value in the Falloff spinner. The deformation outside the volume is a continuous extrapolation of the deformation inside the volume. The deformation can be extreme for points far away from the source lattice.

Falloff—This spinner, enabled only when you choose All Vertices, determines the distance from the lattice that the FFD effect will decrease to zero. When this spinner is set to 0, it's effectively turned off, and there is no falloff; that is, all vertices are affected regardless of their distance from the lattice. The units of the Falloff parameter are specified relative to the size of the lattice: A falloff of 1 means that the effect will go to 0 for points that are a lattice width/length/height away from the lattice (depending on which side they are on).

Tension/Continuity—Lets you adjust the tension and continuity of the deformation splines. Although you can't see the splines in an FFD, the lattice and control points represent the structure that controls the splines. As you adjust the control points, you alter the splines (which move through each point). The splines, in turn, deform the geometry of the object. By altering the tension and continuity of the splines, you alter their effect on the object.

Selection group
These options provide additional methods of selecting the control points. You can toggle the state of any combination of the three buttons to select in one, two, or three dimensions at once.

All X, All Y, All Z—When one of these buttons is on and you select a control point, all control points along the local dimension specified by the button are selected as well. By turning on two buttons, you can select all control points in two dimensions.

About—Displays a dialog with copyright and licensing information.

---

FFD(Cyl) Space Warp

Free-form deformations (FFDs) provide a method of deforming an object by adjusting the control points of a lattice. The offset position of the control points to the original lattice source volume causes the distortion of the affected object.

The FFD(Cyl) space warp uses a cylindrical array of control points in its lattice. This FFD is available as both an object modifier and a space warp. For information on the object modifier version, see FFD (Box/Cylinder) Modifiers (page 1–685).

You create FFD space warps as separate objects similar to the way you create standard primitives: by dragging the mouse in the viewport. The result is a lattice of control points. The source lattice of an FFD modifier is fitted to the geometry it’s assigned to in the stack. This might be a whole object or a sub-object selection of faces or vertices.

Because FFD space warps are separate objects, they carry their own adjustable dimension parameters among the creation parameters.

You can apply object modifiers to space warp objects. For example, you can use the Linked XForm modifier with a space-warped FFD.
Procedures

Example: Create an animated tablecloth:

Finished tablecloth using FFD (Cyl) space warp

This example shows how to use the FFD(Cyl) space warp to create a tablecloth that flies in and drapes itself over a table.

Begin by creating the table and tablecloth.

1. Create a table from two cylinders. Make the table top with a radius of 30 units, and a height of 2 units. Make the "table stand" cylinder with a radius of 3 and a height of 60.

2. Make a tablecloth from a box 100 units square and 0.5 units in height. Increase Length and Width Segments to 30, and keep Height Segments at 1.

3. Position the tablecloth so it’s level with or slightly above the table top, and a little less than 100 units to the left of the table edge, as seen from the Top view.

4. Apply a nice wood grain to the table, and a checker to the tablecloth. (Set the checker tiling to about 15x15, and choose any color for the checkers.)

Now, set up a cylindrical FFD space warp that will form the drape of the tablecloth over the table.

1. From the Create panel > Space Warps > Geometric/Deformable, choose FFD(Cyl).

2. In the Top viewport, create a cylindrical FFD space warp, centered on the table top, with a radius of 45 and a height of 5.

3. Click the Set Number of Points button and, in the Set FFD Dimensions dialog, set Side points to 12, Radial points to 5, and Height points to 2.

4. Move the entire FFD lattice up until it’s just over the surface of the table, as seen from the Front viewport.

Next, adjust the control points of the lattice to drape over the table.

1. Zoom Extents All Selected.

2. On the Modify panel, in the stack display (below "Modifier List"), click the FFD(cyl) item so it turns yellow. This means you’ve enabled direct access to the FFD space warps control point sub-objects.

3. In the FFD Parameters rollout > Selection group, turn on All X. This lets you select control points around the perimeter of the FFD cylinder.

4. In the Top viewport, use the Select and Move tool (page 1–439) and region-select the two visible control points of the two outer rings of control points at the nine-o’clock position. (This is easier shown than described. You can actually region-select any number of vertices in the two outer concentric rings of vertices.)
Because All X is on, all control points for the two rings will be selected.

5. On the status bar, click the Selection Lock Toggle button to lock the selection. In the Front viewport, drag the selected points halfway down the height of the table.

6. Unlock the selection, and then region-select any control point in the outer ring to select all points in the outer ring.

7. Lock the selection and, in the Front viewport, drag the outer ring of points down to the floor.

You now have a truncated cone shape over the table.

8. Unlock the selection. In the Top viewport, again select all the control points in the two outer rings.

9. Scale the selected control points in, until the radius of the inner ring of points is slightly larger than the table top.

10. Select only the outer ring of points, and scale them so their radius is slightly larger than the inner ring.

If necessary, move the points, as seen from the Front viewport, down to touch the floor again. You now have a lattice of control points draped over the table.

In this next series of steps, you’ll bind the tablecloth to the FFD lattice, and then animate it to move over the table.

1. In the stack display, click the FFD(cyl) entry again to exit the sub-object level. It turns gray.

2. In the main toolbar, click the Bind to Space Warp button, and drag between the FFD and the tablecloth.

3. Select the FFD lattice.

4. Choose Deform group > All Vertices.

The tablecloth is immediately deformed because all vertices are now affected, including those outside the lattice volume, and Falloff is set to 0. A falloff value of 0 means that the distance of the vertices from the lattice doesn’t matter. Any number greater than 0, however, limits the effect.

5. Set the Falloff spinner to 0.4.

No longer influenced by the FFD space warp, the tablecloth returns to its square shape.

6. Turn on Auto Key, and go to frame 100.

7. In the Top viewport, select the tablecloth, and move it until it’s centered over the table.

8. As the tablecloth nears the table, it droops down to the floor, sweeps up and over the table, and finally drapes itself over the table.
9. As you move the time slider back and forth and examine the animation, you might find that the bottom of the tablecloth is deformed to the point where it’s hanging below the floor. To fix this, turn off Auto Key, go to frame 100, select the lower ring of control points, and move them up until the tablecloth is at the height you want it. You can also adjust the position of the other control points to create drapes, and so on.

10. On the Display command panel > Hide by Category rollout, turn on Space Warps to hide the FFD space warp.

11. Set up appropriate lights and a camera, and play your animation.

Interface

This rollout lets you set the size and resolution of the lattice, and how it displays and deforms.

Dimensions group

These options let you adjust the unit dimensions of the source volume, and specify the number of control points in the lattice. Note that the point dimensions are displayed beside the modifier name in the Stack list.

Radius, Height—These two spinners display and let you adjust the length, width, and height of the lattice. To create the space warp, drag the mouse in the same way that you would to create a standard
Cylinder primitive. Note that these spinners don’t exist in the object-modifier version of the FFD.

**Label**—Displays the current number of control points in the lattice (for example: 4x8x4).

**Set Number of Points**—Displays a dialog containing three spinners labeled Side, Radial, and Height, plus OK/Cancel buttons. Specify the number of control points you want in the lattice, and then click OK to make the change.

**Side**—The number of control points around the perimeter of the lattice.

**Radial**—The number of control points, radially, from the center to the outer perimeter of the lattice.

**Height**—The number of control points along the height of the lattice.

Note: Make changes to the dimensions before you adjust the positions of the lattice control points. When you change the number of control points with this dialog, any adjustments you’ve already made to the control points are lost; however, you can undo this use of the dialog.

**Display group**

These options affect the display of the FFD in viewports.

**Lattice**—When on, lines are drawn connecting the control points to make a grid. Although viewports can become cluttered when these extra lines are drawn, they help to visualize the lattice.

**Source Volume**—When on, the control points and lattice are displayed in their unmodified state. This display is helpful when you’re adjusting the source volume to affect specific vertices that lie within or without it. See the All Vertices and Only in Volume options, later in this topic.

**Deform group**

These options provide controls that specify which vertices are affected by the FFD.

**Only In Volume**—When on, only vertices that lie inside the source volume are deformed. Vertices outside the source volume are not affected. This is the default choice.

**All Vertices**—When on, all vertices are deformed regardless of whether they lie inside or outside the source volume, depending on the value in the Falloff spinner. The deformation outside the volume is a continuous extrapolation of the deformation inside the volume. Note that the deformation can be extreme for points far away from the source lattice.

**Falloff**—This spinner, enabled only when you choose All Vertices, determines the distance from the lattice that the FFD effect will decrease to zero. When this spinner is set to 0, it’s effectively turned off, and there is no falloff; that is, all vertices are affected regardless of their distance from the lattice. The units of the Falloff parameter are specified relative to the size of the lattice: A falloff of 1 means that the effect will go to 0 for points that are a lattice width/length/height away from the lattice (depending on which side they are on).

**Tension/Continuity**—Let’s you adjust the tension and continuity of the deformation splines. Although you can’t see the splines in an FFD, the lattice and control points represent the structure that controls the splines. As you adjust the control points, you alter the splines (which move through each point). The splines, in turn, deform the geometry of the object. By altering the tension and continuity of the splines, you alter their effect on the object.

**Selection group**

These options provide additional methods of selecting control points. You can toggle any combination of the three buttons to select in one, two, or three dimensions at once.

**All X, All Y, All Z**—When one of these buttons is on and you select a control point, all control points
along the local dimension specified by the button are selected as well. By turning on two buttons, you can select all control points in two dimensions.

About—Displays a dialog with copyright and licensing information.

**Wave Space Warp**

Create panel > Space Warps > Geometric/Deformable > Object Type rollout > Wave

Create menu > Space Warps > Geometric/Deformable > Wave

The Wave space warp creates a linear wave through world space. It affects geometry and behaves the same as the Wave modifier (page 1–957). Use the Wave space warp when you want the wave to affect a large number of objects, or to affect an object relative to its position in world space.

*Using a wave to deform a box*

**See also**

Ripple Space Warp (page 2–102)

**Procedure**

To create a Wave space warp:

1. On the Create panel, click Space Warps. Choose Geometric/Deformable from the list, then on the Object Type rollout, click Wave.

2. Drag in a viewport to define the initial size of the wave object icon. The icon is displayed as a flat mesh wireframe.
3. Release the mouse button to set the icon size; then move the mouse to define the initial amplitude of the wave.

4. Click to set the wave amplitude.

**Interface**

<table>
<thead>

<tr>
<td></td>
<td>Divisions: 10</td>
</tr>
</tbody>
</table>

The initial amplitude sets both Amplitude 1 and Amplitude 2. Set these parameters to unequal values to create a cross wave.

**Wave group**

These options control the wave effect.

- **Amplitude 1**—Sets wave amplitude along the wave warp object’s local X axis.
- **Amplitude 2**—Sets wave amplitude along the wave warp object’s local Y axis.

Amplitude is expressed in units. The wave is a sine wave along its Y axis and parabolic along its X axis. Another way to think of the difference between the amplitudes is that Amplitude 1 is at the center of the wave gizmo and Amplitude 2 is at the edge of the gizmo.

- **Wave Length**—Sets the length of each wave along the wave’s local Y axis, in active units.
- **Phase**—Offsets the phase of the wave from its origin at the wave object’s center. Whole values have no effect; only fractional values do. Animating this parameter makes the wave appear to travel through space.
- **Decay**—When set to 0.0, the wave has the same amplitude or amplitudes throughout world space. Increasing the Decay value causes amplitude to diminish as distance increases from the position of the wave warp object. Default=0.0.

**Display group**

These options control the geometry of the Wave warp gizmo. In some cases, such as when the two Amplitude values differ, they change the effect of the wave.

- **Sides**—Sets the number of side segments along the wave object’s local X dimension.
- **Segments**—Sets the number of segments along the wave object’s local Y dimension.
- **Divisions**—Adjusts the size of the wave icon without altering the wave effect as scaling would.

**Flexibility parameter (Modify panel)**

The Wave space warp also has a Flexibility parameter that you can adjust individually in each bound object’s stack, at the Wave Binding level. The parameter belongs to each binding; it doesn’t appear with the Wave warp parameters.
Flexibility—Makes the bound object more or less responsive to the wave by multiplying the amplitude by this value.

Ripple Space Warp

Create panel > Space Warps > Geometric/Deformable > Object Type rollout > Ripple

Create menu > Space Warps > Geometric/Deformable > Ripple

Using a ripple to deform a surface

The Ripple space warp creates a concentric ripple through world space. It affects geometry and behaves the same as the Ripple modifier (page 1–783). Use the Ripple space warp when you want the ripple to affect a large number of objects, or to affect an object relative to its position in world space.

See also

Wave Space Warp (page 2–100)

Procedure

To create a Ripple space warp:

1. On the Create panel, click Space Warps. Choose Geometric/Deformable from the list, then on the Object Type rollout, click Ripple.
2. Drag in a viewport to define the initial size of the ripple object icon. The icon is displayed as a wireframe spider web.
3. Release the mouse button to set the icon size, and then move the mouse to define the initial amplitude of the ripple wave.
4. Click to set the wave amplitude.

Interface
The amplitude value set by dragging applies equally in all directions. The ripple’s Amplitude 1 and Amplitude 2 parameters are initially equal. Set these parameters to unequal values to create a ripple whose amplitude varies relative to the local X and Y axes of the space warp.

Ripple group

**Amplitude 1**—Sets ripple amplitude along the ripple warp object’s local X axis. Amplitude is expressed in active units.

**Amplitude 2**—Sets ripple amplitude along the ripple warp object’s local Y axis. Amplitude is expressed in active units.

**Wave Length**—Sets the length of each wave, in active units.

**Phase**—Offsets the phase of the wave from its origin at the ripple object’s center. Whole values have no effect; only fractional values do. Animating this parameter makes the ripple appear to travel through space.

**Decay**—When set to 0.0, the ripple has the same amplitude or amplitudes throughout world space. Increasing the Decay value causes amplitude to diminish as distance increases from the position of the ripple warp object. Default=0.0.

Display group

The options control display of the Ripple warp object’s icon. They don’t change the effect of the ripple.

**Circles**—Sets the number of circles in the ripple icon.

**Segments**—Sets the number of segments (pie slices) in the ripple icon.

**Divisions**—Adjusts the size of the ripple icon without altering the ripple effect as scaling would.

Flexibility parameter (Modify panel)

The Ripple space warp also has a Flexibility parameter that you can adjust individually in each bound object’s stack, at the Ripple Binding level. The parameter belongs to each binding; it doesn’t appear with the Ripple warp parameters.

Flexibility—Makes the bound object more or less responsive to the wave by multiplying the amplitude by this value.

Conform Space Warp

Create panel > Space Warps > Geometric/Deformable > Object Type rollout > Conform

Create menu > Space Warps > Geometric/Deformable > Conform

The Conform space warp modifies its bound object by pushing its vertices in the direction indicated by the space warp icon, until they hit a specified target object, or until the vertices move a specified distance from their original position.

After creating a Conform space warp, you specify a target object in the Conform parameters, and then bind the Conform to the object you want to deform. You rotate the Conform icon to specify
the travel direction (toward the target object). The vertices of the deformed object move until they hit the target object.

There is also a Conform compound object (page 1–324) that provides additional methods of conforming one object to another.

Conform viewport icon (a surface is below it)

Procedures

Example: Using the Conform space warp:

Begin by making two objects.

1. Create a terrain by making a wide, flat box with plenty of Length and Width segments (or a quad patch). Apply a Noise modifier and adjust its parameters to result in a bumpy terrain (not mountainous, but low and irregular).

2. Create a short, wide cylinder whose radius is about one-eighth the area of the box (like a coin). You’ll animate the cylinder to float diagonally over the surface of the terrain.

3. Set Cap Segments in the cylinder to 4, and position the cylinder to float over the terrain.

4. Set the object color of the cylinder to contrast with the color of the terrain.

5. Move the cylinder inside one corner of the terrain as seen from the Top viewport. Turn on Animate, move to frame 100, and move the cylinder to the opposite corner of the terrain.

The coin/disk moves from one corner of the terrain to the other.

The terrain will become the target object, and the cylinder the deformed object. The next step is to create the Conform space warp and bind it to the cylinder.

1. On the Create panel, choose Space Warps, and then, from the drop-down list, choose Geometric/Deformable. Click the Conform button.

2. In the Top viewport, in the center of the terrain, drag outward to create the Conform space warp.

3. Click the Pick Object button, and then click the terrain box.

4. In the Front viewport, drag the space warp up until it’s above the cylinder.

As seen in the Front viewport, the terrain is at the bottom, the cylinder is between the terrain and the space warp, and the space warp is at the top.

5. Bind the space warp to the cylinder.

The cylinder becomes a disk that seems to be painted on the surface of the terrain.

6. Drag the time slider to see the cylinder/disk move across the box, following the terrain.

Because the vertices are pushed almost to the level of the terrain, the faces of the two object might intersect. In the following steps, you’ll fix this by adjusting the standoff distance between the target surface and the pushed vertices. Then you’ll go on to affect only selected vertices in the cylinder.

1. Select the Conform space warp, and open the Modify panel.

2. Set Standoff Distance to 3.

You can now clearly see the surface of the disk above the terrain.

3. Set the Standoff Distance to 20.
The disk floats 20 units above the terrain. Next, change the affected vertices.

4. Select the disk/cylinder.
5. In the modifier stack display, click the Cylinder item so it's highlighted in gray.
6. Apply a Mesh Select modifier.
7. At the Vertex sub-object level, in the Front viewport, region-select the bottom cap vertices of the cylinder.
8. Remain at the sub-object level, and in the stack display click the Conform Binding item.
9. In the viewport, select the Conform icon.
10. In the Modify panel, turn on Use Selected Vertices.

Now that only the bottom cap vertices are selected, the rest of the cylinder is restored. If you adjust the viewing angle and play the animation, you'll see that the bottom face of the cylinder follows the terrain, while the rest of the cylinder retains its shape.

**Interface**

Wrap To Object group

These options provide controls to select the target object.

**Pick Object**—Click this, and then select an object in the scene. The object you select becomes the barrier against which the bound object’s vertices will be pushed.

**Object**—Displays the name of the picked object.

Move Vertices group

These options affect how the vertices are moved.

**Default Projection Distance**—The distance a vertex in the bound object moves from its original location if it does not intersect the target object.

**Standoff Distance**—The distance maintained between the vertex and the surface of the target object. For example, if set to 5, the vertices can be pushed no closer than 5 units from the surface of the target object.

**Use Selected Vertices**—When on, only the sub-object selection of vertices on the Stack are pushed. When off, all vertices in the object are pushed regardless of the Stack selection.

Display group

**Icon Size**—Specifies the size of the icon.

**Bomb Space Warp**

The Bomb space warp explodes objects into their individual faces.
Chapter 11: Space Warps and Particle Systems

Procedure

To create a Bomb space warp:

1. On the Create panel, click Space Warps. Choose Geometric/Deformable from the list, and then on the Object Type rollout, click Bomb.

2. Create mesh objects to be exploded.

3. On the toolbar, click the Bind to Space Warp button.

4. Drag the mouse between each object and the Bomb space warp.

5. Adjust Bomb parameters to achieve different effects.

Interface

Explosion group

Strength—Sets the power of the bomb. Larger values make the particles fly farther. The closer an object is to the bomb, the greater the effect of the bomb.

Spin—The rate at which fragments rotate, in revolutions per second. This is also affected by the Chaos parameter (which causes different fragments to rotate at different speeds), and by the Falloff parameter (which causes the force of the explosion to be weaker the farther the fragment is from the bomb).

Falloff—The distance from the bomb, in world units, of the effect of the bomb. Fragments past this distance are not affected by the Strength and Spin settings, but are affected by the Gravity setting.

For example, this is useful for blowing up the base of a building, and having the top of the building topple. To see the effect, place a bomb at the base
of a tall cylinder with many height segments, and adjust Falloff to be less than the height of the cylinder.

**Falloff On**—Turn on to use the Falloff setting. The falloff range appears as a yellow, tri-hooped sphere.

**Fragment Size group**
These two parameters define the number of faces per fragment. Any given fragment will have a number of faces, randomly determined, between the Min and Max values.

**Min**—Specifies the minimum number of faces per fragment to be randomly generated by the "explosion."

**Max**—Specifies the maximum number of faces per fragment to be randomly generated by the "explosion."

**General group**

**Gravity**—Specifies the acceleration due to gravity. Note that gravity is always in the direction of the world Z axis. You can have negative gravity.

**Chaos**—Adds random variation to the explosion to make it less uniform. A setting of 0.0 is totally uniform; 1.0 is a realistic setting. A value greater than 1.0 makes the explosion extra chaotic. Range=0.0 to 10.0.

**Detonation**—Specifies the frame at which the bomb goes off. Bound objects are unaffected before this time.

**Seed**—Change to alter randomly generated numbers in the bomb. You can achieve a different bomb effect by changing Seed while maintaining the other settings.

Although you can animate strength and gravity, the equations used for projectile motion assume they are constant. Therefore, the motion will not be physically correct, but it might look interesting.

Also, if the bomb object is in motion during the blast, the result is not physically correct.

---

**Modifier-Based**

Create panel > Space Warps > Modifier-Based

Create menu > Space Warps > Modifier-Based

Modifier-based space warps duplicate the effects of standard object modifiers. Like other space warps, they must be bound to objects, and they work in world space. They are useful when you want to apply effects such as Twist or Bend to a widely scattered group of objects.

**Creating Modifier-Based Space Warps**

You create modifier-based space warps the same way that you create other space warps. Modifier-based space warps are listed on the Create panel as a separate category under Space Warps.

All the modifier-based space warps use a box-shaped (nonrenderable) object. When you create one, you use the mouse in the viewport as you do when creating a Box primitive.

Unlike their modifier versions, these space warps do not have sub-object levels.
Chapter 11: Space Warps and Particle Systems

Interface
Gizmo Parameters rollout

- Gizmo Size group
  Length/Width/Height—Let you adjust the warp object’s dimensions.

- Deformation group
  Decay—When is set to 0, there is no decay, and the space warp affects its bound object regardless of its distance from the object. When you increase the decay, the effect on the bound object falls off exponentially. See the topics on the individual modifiers for more information.

Parameter rollout
The parameters for a modifier-based space warp are identical to those of the modifier on which the space warp is based:
Bend Modifier (page 1–560)
Taper Modifier (page 1–863)
Noise Modifier (page 1–743)
Twist Modifier (page 1–876)
Skew Modifier (page 1–790)
Stretch Modifier (page 1–836)

Particle Systems
Particle systems are useful for a variety of animation tasks. Primarily, they’re employed when animating a large number of small objects using procedural methods; for instance, creating a snowstorm, a stream of water, or an explosion. 3ds Max provides two different types of particle systems: event-driven and non-event-driven. The event-driven particle system, also known as Particle Flow (page 2–109), tests particle properties, and, based on the test results, sends them to different events. Each event assigns various attributes and behaviors to the particles while they’re in the event. In the non-event-driven systems (page 2–237), particles typically exhibit similar properties throughout the animation.

Important: Particle systems can involve a great many entities, each of which is potentially subject to any number of complex calculations. For this reason, when using them for advanced simulations, you should have a very fast computer and as much memory as possible. Also, a powerful graphics card helps speed the display of particle geometry in the viewports. Even so, it’s still easy to overburden the system; if you encounter loss of responsiveness, wait for the particle system to finish its calculations, and then reduce the number of particles in the system, implement a cache, or use other methods to optimize performance.

Which Particle System to Use?
Having access to a wealth of particle systems in 3ds Max leads to the need to decide which system to use for a particular application. In general, for a simple animation, such as falling snow or a water fountain, setup is faster and easier with a non-event-driven particle system. With more complex animations, such as an explosion that generates different types of particles over time (for example: fragments, fire, and smoke), use Particle Flow for greatest flexibility and control.
Particle Flow

Particle Flow is a new, extremely versatile and powerful particle system for 3ds Max. It employs an event-driven model, using a special dialog called Particle View (page 2–125). In Particle View, you combine individual operators (page 3–985) that describe particle properties such as shape, speed, direction, and rotation over a period of time into groups called events (page 3–935). Each operator provides a set of parameters, many of which you can animate to change particle behavior during the event. As the event transpires, Particle Flow continually evaluates each operator in the list and updates the particle system accordingly.

To achieve more substantial changes in particle properties and behavior, you can create a flow (page 3–942). The flow sends particles from event to event using tests (page 3–1021), which let you wire (page 3–1033) events together in series. A test can check, for example, whether a particle has passed a certain age, how fast it’s moving, or whether it has collided with a deflector. Particles that pass the test move on to the next event, while those that don’t meet the test criteria remain in the current event, possibly to undergo other tests.

Note: Operators and tests are known collectively as actions (page 3–903).

Following are the principal sections in the Particle Flow documentation:

Using Particle Flow (page 2–109)

Particle Flow User Interface (page 2–125)

Actions (page 2–141)

The Particle Flow Tutorials.

See also

Non-Event-Driven Particle Systems (page 2–237)
To add an action to the particle diagram, you drag it to the event display from the depot (the area at the bottom of the Particle View dialog). If you drag an action to an event, you can add it to the event or replace an existing action, depending on where you drop it. If you drop it in an empty area, it creates a new event. Then, to customize the action, you click its event entry, and then edit its settings in the parameters panel at the side of Particle View.

To add complexity to the particle system, you can add a test to an event, and then wire the test to another event. You can adjust the test parameters to affect particle behavior, as well as determine whether specific conditions exist. When particles meet these conditions, they become eligible for redirection to the next event.

Particle Flow provides a number of tools for determining where in the system particles currently reside, including the ability to change particle color and shape on an event-by-event basis. You can also easily enable and disable actions and events, and determine the number of particles in each event. To speed up checking particle activity at different times during the animation, you can cache particle motion in memory. Using these tools, plus the ability to create custom actions with scripting, you can create particle systems of a level of sophistication previously unachievable.

The Life of a Particle

Another way of looking at Particle Flow is from the perspective of an individual particle. Each particle first comes into existence, or is born, via the Birth operator (page 2–143), which lets you specify when to start and stop creating particles, and how many to create.

The particles first appear at an object called an emitter. By default, the emitter is the Particle Flow source icon using the Position Icon operator (page 2–147), but you can alternatively use the Position Object operator (page 2–148) to specify that particles should be born on the surface of or within any mesh object in the scene.

After being born, particles can remain stationary at the emission point, or start moving in two different ways. First, they can move, physically, within the scene at a speed and in a direction specified by various actions. These are typically Speed operators, but other actions can also affect particle motion, including Spin (page 2–154) and Find Target (page 2–218). In addition, you can use the Force operator (page 2–204) to affect their motion with outside forces.
The Life of a Particle

1. Particle immediately after creation, with no speed.
2. The Speed operator sets the particle in motion.
3. The particle continues moving until acted upon by another action.

The second way that particles move is logically, from event to event through the particle diagram, as constructed in Particle View (page 2–125). Each event can contain any number of operators that can affect, in addition to motion, a particle’s surface appearance, its shape and size, and others.

The particles start out in the birth event, which typically is the first event after the global event. During a particle’s residence in an event, Particle Flow evaluates each of the event’s actions from top to bottom, once per integration step, and makes any applicable changes to the particle. If the event contains a test, Particle Flow determines whether the particle tests ‘true’ for the test’s parameters, such as whether it has collided with an object in the scene. If it does, and if the test is wired to another event, Particle Flow sends the particle to the next event. If it doesn’t, the particle remains in the current event, and may be further acted upon by its operators and tests. Thus, each particle exists in only one event at a time.

An action in an event can change the particle shape (1), or the particle spin (2), or spawn new particles (3).

Actions can also apply forces to particles (1), specify collision effects (2), and alter surface properties (3).

In this way, the particle continues to travel through the system. Due to the flexible nature of schematic construction in Particle Flow, a particle may be redirected to the same event several times. But at some point, you might want the particle’s life to end. For this purpose, you’d use the Delete operator (page 2–146) or the Collision Spawn test (page 2–215) or Spawn test (page 2–230). Otherwise, the particle lives throughout the entire animation.

Particle age can be used to kill a particle.

As a particle moves through the system, it’s accompanied by a number of channels. For example, each particle has a speed channel that defines how fast it moves, and a material ID channel that lets Particle Flow know which sub-material to apply to it. However, the material itself is not defined by a channel, but by a Material operator that acts locally or globally. Properties that are defined by channels persist, unless altered by an action. For example, the Material Dynamic operator (page 2–191) can change a particle’s material ID. In effect, by setting up a particle diagram and modifying how particles look and act during the animation, you’re deciding how channel values change based on events and animation keyframes.
Introductory Tutorial

The best way to understand Particle Flow is by using it. This tutorial will acquaint you with some of the basic methods of working with Particle Flow.

Create the Particle Flow system:
1. Start 3ds Max or reset the program.
2. On the Create panel > Geometry category, click the drop-down list and choose Particle Systems.
3. On the Object Type rollout, click PF Source.
4. In the Perspective viewport, drag out a rectangle.
5. Drag the time slider.
6. Go to frame 10, and press \[\text{Shift}+\text{Q}\] to render the Perspective viewport.

By default, the icon emits particles downward from its entire surface. In the viewport, the particles appear as ticks.

This is the Particle Flow icon, or source, named PF Source 01. By default, it acts as an emitter, but you can also use any other object as an emitter.
The rendered particles appear in a window. The default particle shape is a tetrahedron, a four-sided triangular solid. Its geometry is very simple, so the system can handle many particles quickly and efficiently, but it gives a good idea of how particles are behaving. Other basic shapes are a low-poly sphere and a cube; Particle Flow also lets you use any scene object as particle geometry.

**Modify the particle system in Particle View:**

1. Press the key to open Particle View. The particle source icon need not be selected.
   Tip: You can also open Particle View from the command panel when a Particle Flow source icon is selected.

Particle View is where you manage and edit the particle system. The main window, known as the *event display*, contains the *particle diagram*, which describes the particle system. The default system starts with a *global event*, with the same name as the Particle Flow icon, followed by a *birth event*, containing a Birth operator and several others that define the system’s initial properties. Each operator’s name is followed by its most important setting or settings in parentheses. Above the event display is a menu bar, and below is the *depot*, containing all operators available for use in the particle system. For more information about this dialog, see Particle View.
2. In the global event, PF Source 01, click the name of the Render 01 (Geometry) operator to highlight it and access its parameters. Be sure to click the text area; clicking the icon simply toggles the operator’s active state.

Because this operator is in the global event, it affects the entire particle system. Any operator you place here does likewise. For example, you can define a global material here, or you can define different materials locally in each event. For best results, don't combine global and local operators of the same type in a single system; use one or the other.

The settings for the Render operator appear in a rollout on the parameters panel, on the right side of the Particle View dialog. These include a drop-down list for how particles are to render, the percentage of particles that will render, and how to split up the particles into individual meshes.

Next, you’ll change the particle display type.

3. In the birth event, Event 01, click the Display 01 (Ticks) operator at the bottom of the list.

The display type is set to Ticks, as noted in the operator name in the event.

4. Next to the Type label, click Ticks, and from the drop-down list, choose Geometry.

Now the particles appear as tetrahedrons in the viewports.

Wire two events together:

Next, you’ll add a test and use it to wire the birth event to a new event.

1. In the depot at the bottom of the Particle View dialog, find Age Test. It’s the first item that uses a yellow, diamond-shaped icon.

2. Drag an Age Test from the depot into the Event 01 list, at the bottom of the list.
Before you release the mouse button, make sure you see a solid blue line in Event 01 under the Display operator. If the line is red and goes through an existing operator, the Age Test will replace that operator. If you drop the Age Test outside of Event 01 it will create a new event.

The test type is Particle Age, so this means that all particles that have existed for more than 15 frames will test True, and be passed on to the next event.

Next, you'll create a new event and wire it to the test.

4. From the depot, drag the Shape operator ("Shape") to an empty part of the event display, below Event 01.

Age Test appears in the list, with its test output sticking out to the left. This is the part you use to connect the test to the next event.

3. Click the Age Test item in the list, and then in the Age Test 01 rollout on the right side of Particle View, set Test Value=15 and Variation=0.
116 Chapter 11: Space Warps and Particle Systems

The Shape operator appears in a new event, named Event 02. Like Event 01, the event has a circular event input sticking out from the top. Also, Particle Flow automatically adds a local Display operator to the event so its particles will be visible in the viewports. You can disable the automatic creation of local Display operators by choosing Options menu > Default Display > Global.

The actual location of an event in the event display doesn’t matter; the recommended placement is for the sake of convenience when wiring the events. It also helps to make sense of complex schematics if the events are arranged logically.

You can move an event by dragging its title bar.

Next, you’ll perform the actual wiring of the Age Test to the new event.

5. Position the mouse cursor over the blue dot at the left end of the Age Test’s test output.

The cursor image changes to an icon depicting three arrows pointing inward toward a circular connector.

6. Drag from the event output on the Age Test in Event 01 to the Event 02 input, and then release the mouse button.
As you drag, the cursor image changes from a three-arrow icon to a circular connector by itself when it's over an empty space in the event display area, and then to a four-arrow icon when it's over the Event 02 input.

When you release the mouse button, a blue “wire” appears connecting the two events. This wire indicates that particles that meet the Age Test conditions will pass “through” this wire to Event 02, to be affected by its actions.

Tip: You can delete a wire (and anything else in the particle diagram) by selecting it and pressing the [Delete] key. Feel free to try this now, but undo any changes when you're finished.

7. Click the Shape 02 operator and set Shape=Cube. Also, click the Display 02 operator and set Type=Geometry.

**View the wiring results:**

1. Play the animation. Adjust the viewports so you can see the entire particle stream, if necessary.

Starting at frame 16, the particles at the head of the stream change into cubes, indicating that they've entered Event 02. As time goes on, more and more particles pass the age of 15 and become eligible to go to the next event.

2. While the animation is playing, try modifying the different operator settings to see what happens. For instance, click Speed 01 and
change the Speed and Direction settings. When you change a setting, the change is reflected in the viewports in real time, even during playback.

Try right-clicking actions and events and using Rename to give them custom names. Even with a custom name, an action’s tooltip reveals its type.

Another facility of the right-click menu is to add comments to actions and events. Once you do so, a small red triangle indicates the comment’s presence.

Congratulations! You now have a working knowledge of Particle Flow. If you’d like to try some more tutorials, please go to this page and download the 3ds Max 8 Tutorials – Online Help (or PDF versions) and the Scene and Support Files.

### Particle Flow FAQ

This topic offers answers to a number of questions users commonly ask when first learning to use Particle Flow. The first section contains links to all the questions, and the subsequent sections contain the questions and answers organized by category.

#### Question List

**How does Particle Flow handle time?** (page 2–119)

When I go to a different frame, the software sometimes seems to freeze for a while. What’s going on? (page 2–119)

**Is there a way to pre-calculate portions of a particle simulation, as in “baking” the animation?** (page 2–120)

**What else can I do to optimize performance?** (page 2–120)

**How do I use Particle Flow to make an object explode?** (page 2–120)

**How can I control the accuracy of the Particle Flow simulation?** (page 2–120)

**Can I use MAXScript to affect particles?** (page 2–120)

**Can I use more than one object as instanced geometry?** (page 2–121)

**How can I exclude particles from certain light sources?** (page 2–121)

Why do my particles lose their material when they move to another event? (page 2–124)

Can I have an event receive input from multiple events? (page 2–124)

I changed an operator setting, but it doesn’t seem to have any effect on the particle system. (page 2–124)

Can an event be isolated in Particle View and not connected to anything? (page 2–124)

General
How does Particle Flow handle time?

Parameters that measure time in Particle Flow, such as Birth (page 2–143) > Emit Start/Stop and Age Test (page 2–211) > Test Value, are specified in frames. However, Particle Flow is always aware of the current system frame rate (fps), and if you change this rate, it adjusts all time-related parameters to keep the same timing. For instance, if you set Test Value to 60 when you’re using the NTSC frame rate (30 fps), and then switch to PAL (25 fps), Particle Flow automatically changes the value to 50, so the age that’s tested for is still two seconds.

On the other hand, rate parameters, such as Speed, are measured in units per second, so they don’t change when you go to a different frame rate.

When I go to a different frame, the software sometimes seems to freeze for a while. What’s going on?

Most of the animation in Particle Flow is history dependent; that is, to be able to draw the particles in a particular frame, the program needs to know what happened in all previous frames. Normally, when you change a parameter value, the program needs to recalculate all frames between the start and the current frames. Or, if you go to a different frame, Particle Flow must recalculate one or more animation frames. If you go forward, it must calculate the frames between the current frame and the one you go to. So, for example, if you just go to the next frame, relatively little calculation is needed. But if you go backward, even only by one frame, it must calculate all frames from the start of the animation to the frame you go to.

If a lot of calculation is needed, there is a delay. Meanwhile, the software displays a message like “PF Source 01 Update xx% (Press Esc to cancel)” in the status bar, so you can get an idea of how the recalculation is progressing. If, when you see this message, you press the Esc key, Particle Flow displays an alert with the message “Click OK to turn off PF Source 01.” If you click OK, the recalculation stops, giving you the opportunity to optimize the animation. For example, you could reduce the number of particles for testing purposes. You must turn the source back on to continue. If you click Cancel, the calculation continues.

Tip: An easy way to speed up recalculation and rendering of particles is by adjusting the total number of particles. To do this, select the Particle Flow source icon, and then go to the Modify panel > Emission rollout > Quantity Multiplier group. Here you can increase or decrease by percentage
the total number of particles, separately for viewport display and rendering.

Tip: To speed up animation playback when you’re not adjusting parameters, use the Cache operator (see the following item).

Is there a way to pre-calculate portions of a particle simulation, as in “baking” the animation?

Yes. Particle Flow’s Cache operator (page 2–197) lets you store all or part of a particle animation in memory, and then play back the animation from memory rather than having to re-calculate particle motion. This makes it much faster to jump between different parts of the animation. You can even save the cached animation to disk as part of the scene file.

What else can I do to optimize performance?

Particle Flow can place heavy processing and resource demands on your computer. For optimal performance, the most important thing you can do is to use the fastest available CPU. Also, when using particle systems with many particles, install as much memory as possible in your computer, especially if you’re using caching.

Other ways to improve performance include reducing the percentage of viewport particles with the Quantity Multiplier setting, and temporarily disabling flows and actions that you’re not currently working with. When making parameter changes, return to the first frame and play forward, or set Particle View > Options menu > Update Type to “Forward”. That way, if you change a setting, the particle system is not forced to re-calculate its state from the very beginning. The change will affect only animation from the current frame forward. On the other hand, the result could be misleading, because you won’t be able to see the difference right away.

Also, be cautious when using spawning; it can quickly create very large numbers of particles, especially when you use the By Travel Distance option in the Spawn test (page 2–230).

How do I use Particle Flow to make an object explode?

Particle Flow doesn’t have a fragmentation operator, but by utilizing PArray in a Birth Script operator, you can implement fragmentation in Particle Flow. You can find an example scene, with a commented script operator, in the file scriptfragmentationwithcache.max, on the install disc in the directory Samples\Scenes\Version6Features\Scenes\Particle Flow\Fragments.

How can I control the accuracy of the Particle Flow simulation?

On the command panel > System Management rollout (page 2–139) of the PF Source icon, you can adjust the integration step independently for viewport playback and rendering. The smaller the integration step, the more times Particle Flow calculates particle motion per frame, resulting in greater accuracy at the cost of calculation time.

Can I use MAXScript to affect particles?

Yes. Particle Flow includes a Script operator (page 2–208) and test (page 2–229), as well as a Birth Script operator (page 2–145), that let you fully customize the particle system. Each scriptable action includes a sample script, which also lists all relevant scriptable functions. You can also control parameters of the Force operator (page 2–204) and Keep Apart operator (page 2–172) with script wiring, described in the respective topics.

In addition, you can execute a script at each integration step, and another just before each frame is viewed or rendered; see Script rollout (page 2–139).
Can I use more than one object as instanced geometry?

Yes. With the Shape Instance operator (page 2–178), you can use groups, hierarchies, and objects consisting of multiple elements, with each member of the combined object constituting a separate particle. These objects can be emitted in a specific order, or in a random order. For example, you can use a text object, with the letters emitted in the order in which they appear in the text.

How can I exclude particles from certain light sources?

To prevent particles from being affected by a light source, use the light’s Exclude function, found on the General Parameters rollout (Modify panel), to specify any events containing particles to be excluded. Specifying the PF Source XX object (default name) has no effect; you must specify all objects listed as PF Source XX->Event XX.

Particle View

How do I open Particle View without clicking Particle View button on the command panel?

Press the 6 key. It might be necessary to first turn on the Keyboard Shortcut Override Toggle.

Do I need multiple Particle Views to manage more than one particle system?

No: All particle systems appear in Particle View. You can scroll and zoom the event display to see the different systems.

Can I selectively disable or ”turn off” portions of a particle system?

Yes. Particle View gives you a number of different ways of doing this. You can click an action’s icon or an event’s light-bulb icon to turn it off, or use the right-click menu, or use Edit menu’s Turn On and Turn Off commands. Also, if you press Esc while Particle Flow is calculating, the software gives you the opportunity of turning off the entire particle system, thus immediately returning control of the software to you. You can then analyze the system to determine the area of slowdown, optimize or simplify the particle flow, and then recalculate the animation.

I sometimes see events named ”Action Recovery” in Particle View. Where did they come from?

When you merge a scene containing Particle Flow data, you can import entire events and isolated actions. If you merge an action without its events, the software places it in an event named “Action Recovery.”

Animation

How do I animate action parameters?

Use the same Auto Key (page 2–278) method as with animating any other parameter in 3ds Max. Note: Avoid animating Particle Flow parameters with Set Key mode or with Shift + right-click. Also, to see animation keys for actions in the track bar, make sure the Particle Flow source icon is selected.

How can I synchronize an animated bitmap texture to particle age?

Use the Material Dynamic operator (page 2–191) in conjunction with the Bitmap 2D map (page 2–1631). You’ll find a procedure that describes the method in detail here (page 2–191).

Do I still need to bind my Particle Flow particles to space warps?

No; you use the Collision test (page 2–212), Collision Spawn test (page 2–215), or Force operator (page 2–204) to affect particle motion with 3ds Max space warps. The ability to do this on a
global and local (per-event) basis gives you much greater control over how space warps affect the particles than with previous systems.

**How do I make particles follow a path?**

You can use the Speed By Icon operator (page 2–162) or the Find Target test (page 2–218), assigning the icon or target to a spline path. You’ll find illustrative procedures in both topics.

**Can I use Snapshot or dynamics with Particle Flow?**

No. The Snapshot tool is not currently compatible with Particle Flow, nor is reactor or the legacy dynamics system.

**How do I use motion blur with Particle Flow?**

You can apply motion blur on a per-event basis by editing the event’s object properties (page 1–117) with the right-click menu in Particle View, or on a global basis by editing the global event’s object properties. In the Particle View dialog, highlight the event to edit and then right-click and choose Properties. On the Object Properties dialog, edit the Motion Blur group settings.

Alternatively, you can apply motion blur to an entire Particle Flow system without the need to set properties by using the multi-pass motion blur effect (page 2–1386) with a camera.

**Note:** You can also use Object Properties to set other properties for events and the particle system, as with any object in 3ds Max. Do this only within Particle View, not using the source icon in the viewports (right-click menu > Properties or Edit menu > Object Properties).

**Note:** When using Object Motion Blur, if an event contains a Material Dynamic operator that uses a material with a Particle Age, Particle MBlur, or Bitmap map, the event should not also contain a Delete operator, or a Spawn or Collision Spawn test. Also, the event should not contain any tests that are wired to another event. The only exception to this is the Age Test operator when set to Absolute Time without any variation; that is, all particles leave the event at the same time. This applies to the use of Object Motion Blur only; there are no restrictions with Image Motion Blur.

**How do I use the Particle Age and Particle MBlur maps with Particle Flow?**

To use the Particle Age map with Particle Flow, you must use the Delete operator to give the particles a finite life span. For further information, see *Delete Operator* (page 2–146).

Also note the following:

- Particle Age, Particle MBlur and a Bitmap map containing an animated bitmap can be used only with *Material Dynamic operator* (page 2–191), with Same As Particle ID turned on. You’ll find procedures for using Bitmap and Particle Age at this topic.

- The particle material cannot be a submaterial; it must be the main material.

- In the non-event-driven particle systems in 3ds Max, Particle MBlur is used with a control named Direction Of Travel\MBlur and an accompanying Stretch parameter. In Particle Flow, you can replicate the stretching effect by using a Scale operator, turning off Scale Factor > Constrain Properties, and scaling the particle along one axis.

I’m trying to apply Particle Flow to an animation created with a dynamics system. Why am I getting strange results such as unexpected spawning of particles?

The dynamics system probably generates rotation keys using the Euler XYZ controller. To avoid interpolation discontinuities, change the rotation controller for such objects to TCB Rotation.
How can I make all particles appear in the first frame while giving them different ages?

Use a negative frame range in the Birth operator (page 2–143). For example, to get a particle-age spread of 30 frames, set Emit Start to -29 and Emit Stop to 0.

How can I specify the time frame in which animated parameters are applied to particles?

You can animate many of the Particle Flow parameter values with keyframing. In most actions, you can choose the time frame by which to apply this animation to the particles from a drop-down list labeled Sync By. You can apply this animation to particles in the time frame of the entire animation, or at a specific time of each particle’s life (particle age), or based on the length of time the particle has been in the current event. See the individual operator and test topics for details.

How can I apply bubble motion to particles?

Although Particle Flow doesn’t have the bubble motion option (page 2–270) found in PArray, you can simulate the effect by following this procedure:

1. Add an object to serve as particle geometry and a dummy helper object (page 2–16).
2. Position the dummy away from the center of the particle geometry object and link (page 2–421) your particle geometry to the dummy so that the dummy is the parent object (that is, drag from the geometry object to the dummy). The distance between the pivots (page 2–487) of the two objects determines the radius of the bubble motion.
3. In Particle View, add a Shape Instance operator (page 2–178) and a Spin operator (page 2–154) to the event in which the bubble motion is to occur.
4. Click the Shape Instance operator and specify the dummy object as the particle geometry object.
5. Click the Spin operator and set appropriate values for Spin Rate and Variation. For Spin Axis, keep the default setting of Random 3D.

The result is particle motion in which the particles bob about while moving along their paths, similar to bubble motion.

Events

How can I branch an event to several other events?

Particle Flow includes several Split tests, which let you send some particles to another event based on quantity, selection, or source. You can use any number of these in a single event to send parts of the particle stream to different events, and then use a Send Out test (page 2–230) to redirect the remaining particles to another event. Keep in mind that any tests subsequent to the first can work only with particles remaining in the event, not necessarily all particles that begin in the event.

Does it matter which order I put actions in an event?

It depends. If an event contains two or more operators of the same type, such as Shape, the last one overrides the rest. If an event contains two or more tests, they are evaluated and particles redirected in the order in which the tests appear.

However, if two actions in an event control the same properties, the interaction is more complex. An action that works on a continuous basis will typically prevail over one that affects particles only when they first enter the event. For example, both the Find Target test (page 2–218) and Speed operator (page 2–159) can control particle speed and direction, but the test works continuously, while the operator takes effect only once. If an event contains both, particle speed and direction
will be primarily controlled by the test, in general, even if the operator comes after the test. However, the operator’s settings will still have some influence over particle behavior, particularly if its Speed value is significantly higher than that of the test. For a list of actions’ effective time frames, see Action Time Frames (page 2–141).

Also, if you’re testing for a specific condition that can be affected by other actions in an event, be sure to place the test after the actions. For example, in an event with a Force operator (page 2–204) and a Collision test (page 2–212), place the Collision test after the Force operator. This avoids the possibility of the force pushing particles past the deflector before the software can test for the collision, which would allow the particles to penetrate the deflector. In general, place tests at the end of the event.

How can I tell which particles are in a certain event?

One way is to set the Type option for the Display operator (page 2–202) in each event to a different choice. For example, the first event could use Ticks, the second Circles, and the third Lines. This way the particles change appearance in the viewports as they move from event to event. You can also use the Display operator to change particle colors, to further distinguish them.

Another way is to select all particles in a certain event. Select the Particle Flow source icon, and then go to the Modify panel > Selection rollout and click the Event icon. You can then click an event in the Select By Event list to highlight all of its particles in the viewports.

Why do my particles lose their material when they move to another event?

A material is a static property of an event. It does not travel along with the particles from event to event. A particle’s material ID does, but its material does not. If you want particles always to use the same material, define the material in the global event (page 3–949) with a Material operator (page 2–186) or a Shape Instance operator (page 2–178). Otherwise, you need to define it in each local event.

Can I have an event receive input from multiple events?

Particle Flow lets you wire any number of tests to a single event.

I changed an operator setting, but it doesn’t seem to have any effect on the particle system.

A similar operator in the global event might be overriding your local operator. By default, Particle Flow evaluates local operators first, and then global operators. If a global operator affects the same property, such as speed, as a local one, the particle system will use the value set by the global operator. You can set local operators to override global ones by choosing Particle View > Options menu > Action Order > Globals First.

Can an event be isolated in Particle View and not connected to anything?

Yes, but it won’t affect the particle system at all.
Particle View provides the main user interface for creating and modifying particle systems in Particle Flow. The main window, known as the event display, contains the particle diagram, which describes the particle system. A particle system consists of one or more events wired together, each of which contains a list of one or more operators (page 2–142) and tests (page 2–210). Operators and tests are known collectively as actions.

The first event is called the global event, because any operators it contains can affect the entire particle system. The global event always has the same name as the Particle Flow icon; by default, this is PF Source ## (starting with 01 and counting upward). Following this is the birth event, which must contain a Birth operator (page 2–143) if the system is to generate particles. By default, the birth event contains this operator as well as several others that define the system’s initial properties. You can add any number of subsequent events to a particle system; collectively, the birth event and additional events are called local events. They’re called this because a local event’s actions typically affect only particles currently in the event.

You use tests to determine when particles are eligible to leave the current event and enter a different one. To indicate where they should go next, you wire the test to another event. This wiring defines the schematic, or flow, of the particle system.

By default, the name of each operator and test in an event is followed by its most important setting or settings in parentheses. Above the event display is a menu bar, and below is the depot, containing all actions available for use in the particle system, as well as a selection of default particle systems.

Tip: The easiest way to open Particle View is by pressing the 6 key. It’s not necessary to first select a Particle Flow icon.

Particle View comprises the following elements:

- The menu bar (page 2–126) provides functions for editing, selection, adjusting the view, and analyzing the particle system.
- The event display (page 2–131) contains the particle diagram, and provides functions for modifying the particle system.
The parameters panel contains rollouts for viewing and editing parameters of any selected actions. Basic functionality is identical to that of rollouts on the 3ds Max command panels, including usage of the right-click menu.

To toggle display of the parameters panel, choose Display menu > Parameters.

The depot contains all Particle Flow actions, as well as several default particle systems. To see an item’s description, click its entry in the depot. To use an item, drag it into the event display (page 2–131).

The contents of the depot fall into three categories: operators (page 2–142), tests (page 2–210), and flows (page 2–208).

To toggle display of the depot, choose Display menu > Depot.

The Description panel displays a brief description of the highlighted depot item.

To toggle display of the description panel, choose Display menu > Description.

The icon-based display tools in the bottom-right corner of the Particle View dialog let you pan and zoom the event display window. For descriptions, see Display menu (page 2–129).

---

**Particle View Menu Bar**

Select a Particle Flow source icon. > Modify panel > Setup rollout > Click Particle View (or press 6).

Create panel > Geometry > Particle Systems > Object Type rollout > Click PF Source. > Setup rollout > Click Particle View (or press 6).

The menu bar provides access to a number of important Particle View functions.

---

**Procedure**

**To render only particles in specific events:**

1. In Particle View, highlight the events containing the particles you want to render.
2. Choose Select menu > Assign Selection To Viewport.
3. Render using one of the Render Type (page 3–13) > Selected options.

**To bring a Particle Flow setup into a different scene:**

1. In Particle View, highlight the events containing the particles you want to merge with a different scene. For example, to designate only a particular flow, you might highlight its global event, and then choose Select menu > Select Downstreams.
2. Choose Select menu > Save Selected, and use the file dialog to specify a file to save.

**Note:** Any scene objects on which Particle Flow depends are also saved. For instance, if a Shape Instance operator (page 2–178) in one of the highlighted events refers to a certain object, that object is saved along with the designated events.

3. Open or create the scene with which the saved Particle Flow setup will be combined, and then use Merge (page 3–463) to merge the file from step 2.

<tr>
<td>Make Unique</td>
<td>Converts an instanced action to a copy that's unique to its event. Available only when one or more instanced actions are highlighted.</td>
</tr>
<tr>
<td>Wire Selected</td>
<td>Wires one or more highlighted tests to a highlighted event, or one or more highlighted global events to a highlighted birth event. Available only when one or more tests and a single event are highlighted, or when one or more global events and a single birth event are highlighted.</td>
</tr>
</tbody>
</table>
| Copy          | Copies any highlighted events, actions, and wires to the paste buffer. Keyboard equivalent: 
                        |                                                                                   |
| Paste         | Pastes the contents of the paste buffer to the event display. Keyboard equivalent: 
                        |                                                                                   |
| Paste Instanced | Pastes the contents of the paste buffer, making instances of any pasted actions and their originals. |

Each of the first three commands on this menu presents a submenu containing all actions. Choose the command, and then choose an action from the submenu.

Note: The Undo and Redo commands are available from the main 3ds Max Edit menu, and their default keyboard shortcuts are the same: Ctrl+Z and Ctrl+Y, respectively.

New—Adds a new event containing the chosen action to the event display.

Insert Before—Inserts the chosen item above each highlighted action. Available only when one or more actions are highlighted.

Append To—Inserts the chosen item at the end of each highlighted event. Available only when one or more events are highlighted.

Turn On All—Turns on all actions and events.

Turn Off All—Turns off all actions and events.

The result of copying and then pasting multiple items depends on what you copied:

- If you copied multiple actions, pasting adds them all to a single new event, even if they originally came from different events.
- Copying multiple events or wires pastes them exactly as copied.
- If you copied a combination of actions and events, pasting creates a new event for each group of actions from a single event. For example, if you highlight event A, some actions from event B, and some actions from event C, copying and then pasting would add three events: a copy of event A, a second event with the actions from event B, and a third event with the actions from event C.

Paste Instanced—Pastes the contents of the paste buffer to the event display, making instances of any pasted actions and their originals.
For the results of pasting multiple copied items, see Paste, above.

**Delete**—Deletes any highlighted items. Keyboard equivalent: Delete

Deleting an event also deletes all of its actions.

**Rename**—Lets you enter a new name for any single highlighted item in the event display. Available only when one action or test is highlighted.

**Select menu**

<table>
<thead>
<tr>
<th>Select Tool</th>
<th>Select All</th>
<th>Select None</th>

<tr>
<td>Assign Selection To Viewport</td>
<td>Sync Source/Events Selection In Viewport</td>
<td></td>
</tr>
</tbody>
</table>

By default, the Select tool is active when Particle View is open, as indicated by the arrow-shaped mouse cursor. You can use this tool to highlight, move, and copy events, actions, tools, and wires. You can also use the commands on this menu to highlight all elements, no elements, or elements by category.

Note: When you render using any of the Selected options, the software renders only events that are selected in the viewports. You can use the last three commands on this menu to manage and coordinate selection of events and flows between Particle View and the viewports. This also applies to use of the Views menu > Shade Selected command.

**Select Tool**—Activates the Select tool. Choose this to return to the Select tool after using interactive tools for panning and zooming the event display. Alternatively, simply right-click anywhere in the event display to activate the Select tool.

**Select All**—Highlights all items in the event display.

**Select None**—Deselects all items in the event display. Alternatively, click an empty area in the event display.

**Select Actions**—Highlights all operators and tests in the event display.

**Select Operators**—Highlights all operators in the event display.

**Select Tests**—Highlights all tests in the event display.

**Select Events**—Highlights all events in the event display.

**Select Wires**—Highlights all wires in the event display.

**Select Downstreams**—Highlights all events after currently highlighted events. Available only when one or more events are highlighted.

**Save Selected**—Saves only highlighted elements in the event display to a .max file. You can then open this file, or combine it with an existing scene with File menu > Merge.

Note: The Particle View > Save Selected command saves all items selected in Particle View and in the scene. So if a PF Source icon is selected in the scene, then this command will save its global event as well as any birth events associated with it. If you want to save only parts of a Particle Flow setup, first unselect everything in the scene.
Also, if an action references an object (for example, a Shape Instance operator (page 2–178) uses a geometry object), and the action or its parent event is highlighted when you use Save Selected, then the reference object is saved as well.

**Get Selection From Viewport**—Highlights global events whose source icons are selected in the viewports.

**Assign Selection To Viewport**— Transfers an event selection to the viewports. Use this to render only particles in specific events. First, in Particle View, highlight the events to render. Next, choose this command, and finally, render using one of the Render Type (page 3–13) > Selected options.

**Sync Source/Events Selection In Viewport**— Selects all events of any source icons selected in the viewports. You can then propagate this selection to Particle View with the Get Selection From Viewport command.

Use this function to render a specific particle flow using one of the Render > Selected options.

**Display menu**

</tbody>
</table>

The first five commands on this menu are also available as icons, in the Display tools section on the right side of the bottom border of the Particle View dialog. Each command’s Display tools icon is shown below.

**Pan Tool**—Drag in the event display to move the view. The mouse cursor changes to a hand icon. You can also pan the view by dragging with the middle mouse button or wheel button held down.

To exit this mode, right-click in the event view or choose the command again.

**Zoom Tool**—Drag in the event display to zoom the view. The mouse cursor changes to a magnifying-glass icon. Drag upward to zoom in, or downward to zoom out.

To exit this mode, right-click in the event view or choose the command again.

**Zoom Region Tool**—Drag in the event display to define a zoom rectangle. The mouse cursor changes to the image of a magnifying glass inside a zoom region. When you release the mouse button, the display zooms to show only the area defined by the region.

To exit this mode, right-click in the event view or choose the command again.

**Zoom Extents**—Sets the zoom to show the entire particle diagram in the event display.

**No Zoom**—Sets the zoom to the default level. This is the level displayed when you first open Particle View in a given session.

**Parameters**—Toggles display of the parameters panel, on the right side of the Particle View dialog. Default=on.

**Depot**—Toggles display of the depot, below the Particle View dialog. Default=on.

**Description**—Toggles the Description panel, to the right of the depot. Default=on.

The Description panel displays a brief description of any action highlighted in the depot.
Options menu

This menu contains a number of options useful in analyzing and debugging particle systems.

**Default Display**—Determines whether the Display operator is applied locally or globally to new particle systems and events. Default=Local.

- **Global**—When you create a new particle system, Particle Flow adds a single Display operator to the global event. It does not add a Display operator to each new event.
- **Local**—Particle Flow adds a Display operator to each new event. This lets you easily distinguish particles in different events in the viewports.

**Action Order**—For predictable results, don’t use similar actions in the global and local events. However, if comparable actions do exist in both the global event and other events, Particle Flow applies them to the system in the order specified here. Typically, the effect that’s applied last is the one that’s visible in the particle system. Default=Locals First.

For example, consider a situation in which the global event contains a Shape operator set to Cube, and the other events in the same system contain Shape operators set to Tetra or Sphere. By default, Particle Flow applies the global Shape operator last at each integration step, overwriting any local shapes, so all particles would be cubes. But if you set Action Order to Globals First, the local shapes are applied last, and particles appear as tetrahedrons or spheres, depending on which event they’re in.

- **Globals First**—At each integration step, Particle Flow first applies actions in the global event, and then actions in the other (local) events. Typically, the result is that actions in the local events override comparable actions in the global event.
- **Locals First**—At each integration step, Particle Flow first applies actions in the local events, and then actions in the global event. Typically, the result is that actions in the global event override comparable actions in the local events.

**Update Type**—This setting determines how Particle Flow updates the system when you change a parameter during playback. Because the state of the particle system at any given frame can depend on events in previous frames, using the Complete option can provide a more accurate depiction of the result of the change, at a cost in speed; it takes more time to recalculate the entire system starting at the first frame. Default=Complete.

- **Complete**—When you change a setting during playback, Particle Flow updates the entire system, starting at the first frame.
- **Forward**—When you change a setting during playback, Particle Flow updates the system starting at the current frame.

**Track Update**—Provides options for visualizing the particle system status in Particle View.

- **Particle Count**—Adds a tab above each event that shows the number of particles in the event. The global event’s count shows the total number of particles in the particle system.
  Use this, in addition to the ability to display particles differently in each event, to trace particle progress through the system.
- **Update Progress**—Highlights each action in color whenever Particle Flow evaluates it. The highlighting is very fast, but this option can add significant computational overhead to the particle system, with the result that
real-time playback might skip a greater number of frames. To see all frames, turn off Time Configuration > Real Time.

**Use Dynamic Names**—When on, action names in events are followed by their most important setting or settings, in parentheses. When off, only the names appear. Default=on.

**Particle View Event Display**

Select a Particle Flow source icon. > Modify panel > Setup rollout > Click Particle View (or press 6).

Create panel > Geometry > Particle Systems > Object Type rollout > Click PF Source. > Setup rollout > Click Particle View (or press 6).

The event display (page 3–936) in Particle View contains the particle diagram, and provides a complete range of intuitive functions for editing the particle system.

Note: A number of these functions are also available from the event display right-click menu (page 2–133), as well as the menu bar (page 2–126).

**Editing the Particle Diagram and Particle System**

Interactive functionality in event display includes the following:

**General**

- To add an action to the particle system, drag it from the depot to the event display. If you drop it in an empty area of the event display, it creates a new event. If you drag it to an existing event, the result depends on whether a red line or a blue line appears when you drop it. If a red line, the new action replaces the underlying action. If a blue line, the action is inserted in the list.
- To edit an action’s parameters, click its name in an event. The parameters appear on the right side of Particle View. If not, it means the parameters panel is hidden; to display it, choose Display menu > Parameters.
- To wire a test to an event, drag from its test output, the blue dot that by default sticks out to the left of the test, to the event’s event input, which sticks out from the top, or vice-versa. Similarly, you can wire a global event to a birth event by dragging between the source output on the bottom of the global event and the event input. The mouse cursor changes to the first depicted image when you can begin this operation, and to the second image when you can complete it.
- To pan or zoom the event display, use the controls available from the Display menu (page 2–129), the right-click menu (page 2–133), or as icons at the bottom-right of the dialog.

**Modifying Actions and Events in the Event Display**

- To change the color used by a Display operator, click its color swatch to the right of its name.
- To toggle an operator (that is, turn it off and on), click its icon in the event. The mouse cursor changes to the depicted image when this action is possible.
- A turned-off operator does not affect the particle system, and appears as gray in the event list; however, its parameters are still available for editing.
- Toggling an instanced operator doesn’t affect its other instances.
- To toggle an event (that is, turn it off and on), click the light-bulb icon next to its name in the title bar. Turning off an event is equivalent to turning off all of its
operators and tests, although you cannot turn
the operators and tests back on individually.
The event’s items do not affect the particle
system, and appear as gray in the event list.
All particles entering a turned-off event are
immediately passed on to the next event, if any.

- To make a test result
always True or False, click its icon’s left or right
side, respectively. The mouse cursor changes to
the first image at the left (with the left-pointing
arrow) when you can click for always True, and
to the second image at the left (without the
left-pointing arrow) when you can click for
always False.

- The test icon changes to a green or
red light bulb to indicate current functionality:
green for always True, and red for always False.

- To return to the original functionality,
click the icon again. The mouse cursor changes
to the depicted image when this action is possible.

Selecting, Moving, and Copying
- To copy an action or event, first press and hold
the [Shift] key and position the mouse cursor
over the item to copy. When the plus sign (+)
appears next to the mouse cursor arrow, drag
the item to a new location. When you release
the mouse button, the Clone Options dialog
appears; choose Copy or Instance and click
OK. In the Clone Options dialog, the Event
And Particle System group is unavailable, as
a reminder that you cannot instance these
elements. Reference is not an option when
cloning Particle System elements. Cloning an
event or particle system simply creates a new
event or particle system containing clones of
the original’s actions.

Any instanced actions have identical properties.
Changing one instance’s values changes them
all. On the other hand, copied actions can have
different values.

- To clone multiple items, highlight them all
before [Shift]-dragging. If you attempt to
copy a combination of actions and events,
or actions from different events, the result
depends on where you start dragging from. If
you drag a highlighted action, you’ll clone only
actions from that event. If you drag an event,
only highlighted events are cloned.

Note: When you highlight an instanced action,
Particle View indicates all of its other instances
by changing their background color to a lighter
shade of gray.

- To move an event, drag its title bar, or the icon
of any of its actions. If you drag the event to an
edge of the display, and scrolling is possible, the
display window will automatically scroll in that
direction.

- To resize an event, drag its right edge.

- To highlight multiple items, drag a rectangle
around them, or [Ctrl]+click them individually.

- To delete an event, action, or wire, highlight it
and then press [Delete]. Be sure the Particle
Dialog is active, or you might inadvertently
delete a selection in the scene instead.

- To move an action, drag its name (not its icon)
to the new location. If you drag the event to an
edge of the display, and scrolling is possible, the
display window will automatically scroll in that
direction.

If you drag an action to an event, you can
insert the action or replace an existing action,
depending on where you position the mouse
cursor before releasing the button. A blue
line (before releasing) indicates that it will be
inserted at that location, and a red line indicates
that it will replace the underlying action. If you
drag the action to an empty space in the event display, it will form a new event, and, by default, the system will add a new Display operator.

Note: Particle Flow doesn’t let you perform illegal operations. For instance, a Birth operator must always be the first item in a birth event (page 3–916); the system doesn’t let you position it elsewhere. You can place a Birth operator in an isolated event, but you can’t then wire that event into a particle system, except in parallel with another birth event. For more information, see the Birth operator topic (page 2–143).

[Image] To move a test output or switch it to the opposite side of the event, drag from just inside the test output to the desired new location. The mouse cursor changes to the depicted image when this operation is possible.

Getting Information

• To see a renamed action’s original type, position the mouse cursor over its event list entry until the tooltip appears.

• To see a brief description of an action, click it in the depot. The description appears on the Description panel, to the right of the depot.

**Event Display Right-Click Menu**

Select a Particle Flow source icon. > Modify panel > Setup rollout > Click Particle View (or press 6). > Right-click in event display.

Create panel > Geometry > Particle Systems > Object Type rollout > Click PF Source. > Setup rollout > Click Particle View (or press 6). > Right-click in event display.

The event display right-click menu provides handy access to a number of contextual commands. The contents of the menu, as well as the results of its commands, depend in some cases on where you click, in other cases on what’s highlighted, and in still other cases, on both.

In the following descriptions, “item” means an action or event, or, in some cases, a wire.

**Interface**

*Insert*—Displays a submenu of all actions, and when you choose a new action, inserts it where you originally right-clicked. Available only when you right-click over an event or action.

If you right-click over an action, and then insert an action, the inserted action replaces the old one. If you right-click above or below an action (no tooltip appears), the new action is added to the event at that location. If you right-click over an event, the action is inserted at the first available position.

*Append*—Displays a submenu of all actions, and when you choose a new action, inserts it at the end of the event. Available only when you right-click over an event or action.

*Turn On*—Turns on the event or action under the mouse cursor. Available only when the item under the mouse cursor is turned on.

To affect an event, the mouse cursor must be over its title bar.

Turning on a highlighted item affects all highlighted items.

*Turn Off*—Turns off the event or action under the mouse cursor. Available only when the item under the mouse cursor is turned off.

To affect an event, the mouse cursor must be over its title bar.

Turning off a highlighted item affects all highlighted items.

*Make Unique*—Converts an instanced action to a copy that’s unique to its event. Available only when the mouse cursor is over an instanced action.
If you right-click over a highlighted, instanced action, Make Unique affects all such actions.

**Wire**—Wires one or more highlighted tests to a highlighted event, or one or more highlighted global events to a highlighted birth event. Available only when one or more tests and a single event are highlighted, or when one or more global events and a single birth event are highlighted, and when you right-click over an eligible, highlighted item.

**Copy**—Copies any highlighted events, actions, and wires to the paste buffer. Available only when the mouse cursor is over an highlighted action, but affects all highlighted items.

**Paste**—Pastes the contents of the paste buffer to the event display at the mouse cursor.

If the cursor is over a list, and you copied actions, the actions are added to the event. If the cursor is over an empty area of the event display, the software creates a new event containing the pasted actions. A copied event can be pasted only in an empty area of the event display.

The result of copying and then pasting multiple items depend on what you copied and the position of the mouse cursor:

- If you copied multiple actions, pasting adds them all to the event under the mouse cursor, or, if the cursor is over an empty area, to a new event, even if they originally came from different events.
- Copying multiple events and/or wires pastes them exactly as copied, but in this case Paste is available only when the mouse cursor is over an empty area.
- If you copied a combination of actions and events, you can paste them only when the mouse cursor is over an empty area. Pasting creates a new event for each group of actions from a single event. For example, if you highlight event A, some actions from event B, and some actions from event C, copying and then pasting would add three events: a copy of event A, a second event with the actions from event B, and a third event with the actions from event C.

**Paste Instanced**—Pastes the contents of the paste buffer to the event display, making instances of any pasted actions and their originals.

For the results of pasting multiple copied items, and the limitations based on mouse position, see Paste, above.

**New**—Add a new item to the event display from the submenu. The submenu contents are identical to that of the depot. Available only when the mouse cursor is over an empty area.

**Delete**—Deletes the item under the mouse cursor. Available only when the mouse cursor is over an item.

If the mouse cursor is over a highlighted item, choosing Delete deletes all highlighted items.

**Rename**—Lets you rename the item under the mouse cursor. Enter a new name from the keyboard.

**Properties**—Opens the Object Properties dialog for the event under the mouse cursor. Available only when the mouse cursor is over the title bar of a highlighted event.

Particle Flow lets you set object properties on a per-event basis. This lets you set attributes such as Hide, Renderable, and Motion Blur separately for each event. Alternatively, you can set properties for the entire particle system from the global event.

For more information, see Object Properties (page 1–117).

Note: Set properties for events and the particle system only within Particle View, not via the source icon in the viewports (using the right-click menu > Properties or Edit menu > Object Properties).
Use Script Wiring—Lets you use a script to specify certain parameters in the Force operator (page 2–204) and Keep Apart operator (page 2–172). This command appears only when you right-click either of the specified, highlighted operators in an event.

Comments—Lets you add comments to each action and event, and view existing comments. Available only when the mouse cursor is over an action or the title bar of an event.

Choosing Comments opens a window for entering text from the keyboard. Begin typing, and click OK to finish. A commented event or action has a red triangle near its name to indicate the presence of the comment. You can click this triangle to open the comment.

Note: A comment is specific to the action or event to which it’s applied. If you copy a commented event or action, the comment is not included in the copy, because it’s probably not applicable to the copy.

Pan—Switches to the Pan tool. Drag in the event display to change the view; right-click to exit. Available only when you click over an empty area of the event display.

Zoom—Switches to the Zoom tool. Drag upward in the event display to zoom in, and downward to zoom out; right-click to exit. Available only when you click over an empty area of the event display.

Zoom Region—Switches to the Zoom Region tool. Drag a rectangle in the event display to specify the area to zoom into; right-click to exit. Available only when you click over an empty area of the event display.

Particle Flow Source

Add a Particle Flow system to the scene. > Create panel
Select a PF Source icon. > Modify panel

Particle View (page 2–125) > Click a global event (title bar). > Parameters panel

The Particle Flow source is the viewport icon for each flow (page 3–942), and also serves as the default emitter. By default, it appears as a rectangle with a central logo (see above illustration), but you can change its shape and appearance using the controls described below.

When you select a source icon in the viewport, the Particle Flow emitter-level rollouts appear on the Modify panel. Alternatively, click the title bar of a global event in Particle View to highlight it, and to access the emitter-level rollouts from the parameters panel on the right side of the Particle View dialog. Use these controls for setting global attributes, such as icon properties and the maximum amount of particles in the flow.
The particle source icon is roughly equivalent to the corresponding global event (page 3–949) in Particle View. They have the same name, but selecting one does not select the other. If you delete a particle source icon from the scene, the software converts the global event to an isolated local event in Particle View, retaining its operators with their settings intact. Any other events in the system remain in Particle View, along with their wiring. However, if you delete a global event, the software also removes any local events used exclusively by that system, as well as the corresponding particle source icon. To retain the local events, first delete the wire from the global event, and then delete the global event.

If you clone a particle source in a viewport with \texttt{Shift} + transform or Edit menu > Clone, an equal number of copies of the global event appear in Particle View, each wired to the original birth event (page 3–916). The Clone Options dialog offers only the Copy option. However, if you clone a global event in Particle View, the Clone Options dialog also lets you create instances of the cloned operators and tests. It's not possible to create instances of global and local events, so these options are unavailable in the Clone Options dialog, as a reminder. Also, global events cloned in Particle View are not automatically wired to the original birth event.

**Interface**

**Modifier stack**

In the modifier stack, expanding the hierarchy of a Particle Flow source object provides access to two sub-object levels: Particle and Event. For further information, see Selection rollout (page 2–138).

**Setup rollout**

![Setup rollout](image)

Use these controls to turn the particle system on and off, and to open Particle View.

**Enable Particle Emission**—Turns the particle system on and off. Default=on.

You can also turn off all particle flows in Particle View with Edit menu > Turn Off All, or a specific particle flow by right-clicking its global event's title bar and choosing Turn Off.

**Particle View**—Click to open the Particle View dialog (page 2–125).

**Emission rollout**

![Emission rollout](image)

Sets the physical characteristics of the emitter (particle source) icon, and the percentage of
particles produced in the viewports and when rendering.

**Emitter Icon group**

**Logo Size**—Sets the size of the Particle Flow logo, which appears at the center of the source icon, as well as the arrow that indicates the default direction of particle motion.

By default, the logo size is proportional to that of the source icon; with this control, you can make it larger or smaller.

This setting affects only the viewport display of the logo; changing it has no effect on the particle system.

**Icon Type**—Choose the basic geometry of the source icon: Rectangle, Box, Circle, or Sphere. Default=Rectangle.

This choice matters only if you use the source icon as the particle emitter. The available size settings depend on which icon type you choose, and, again, are important only if you use the source icon as an emitter.

The default icon type is Rectangle. If you add a particle system, and then change the icon type to Box, the icon continues to resemble a rectangle. To make it look like a box, increase the Height setting.

**Length/Diameter**—Sets the length of the Rectangle and Box icon types, and the diameter of the Circle and Sphere icon types.

**Width**—Sets the width of the Rectangle and Box icon types. Unavailable with the Circle and Sphere icon types.

**Height**—Sets the height of the Box icon type. Available only with the Box icon type.

**Show Logo/Icon**—Turns display of the logo (with arrow) and icon on and off, respectively.

These settings affect only the viewport display of these items; they have no effect on the particle system.

**Quantity Multiplier group**

These settings determine the percentage of the total number of particles in each flow (page 3–942) that are actually produced in the viewports and at render time. They don’t affect the percentage of particles that are visible; those are determined by the Display operator (page 2–202) and Render operator (page 2–206). You can use them to quickly decrease or increase the number of particles consistently throughout all events in the particle system. The maximum setting, 10,000%, lets you multiply the number of particles generated by the flow by 100.

The total number of particles is determined by the combined effects of the following operators and tests: Birth (page 2–143), Birth Script (page 2–145), Delete (page 2–146), Collision Spawn (page 2–215), and Spawn (page 2–230). Scripted operators and tests can also affect this number.

**Viewport**—Sets the percentage of the total number of particles in the system produced in the viewports. Default=50.0. Range=0.0 to 10000.0.

**Render**—Sets the percentage of the total number of particles in the system produced at render time. Default=100.0. Range=0.0 to 10000.0.
Chapter 11: Space Warps and Particle Systems

Selection rollout

Use these controls for selecting particles on a per-particle or event basis. Selection of particles at the Event level is for debugging and tracking purposes. Particles selected at the Particle level can be acted upon by the Delete operator (page 2–146) and the Split Selected test (page 2–235). You cannot directly manipulate selected particles with standard 3ds Max tools such as Move and Rotate.

Note: This rollout appears only on the Modify panel, not on the Create panel or Particle View dialog > parameters panel.

- **Select by Particle ID group**
  - **ID**—Use this to set the ID number of the particle you want to select. You can set only one number at a time.
  - **Add**—After setting the ID number of a particle to select, click Add to add it to the selection. By default, selecting a particle doesn’t deselect any others.
  - **Remove**—After setting the ID number of a particle to deselect, click Remove to remove it from the selection.
  - **Clear Selection**—When on, clicking Add to select a particle deselects all other particles.

- **Get From Event Level**—Click to convert an Event-level selection to the Particle level. Available only at the Particle selection level.

- **Select by Event**—This list shows all events in Particle Flow, and highlights selected events. To select all of an event’s particles, click its list entry, or use standard viewport-selection methods.

- **# Particles Selected**—Shows the number of selected particles.

Selected particles appear in the viewports in red (if not geometry), in the form designated by the Display operator > Selected setting.

Select by Particle ID group

Each particle has a unique ID number, starting with 1 for the first particle and counting up. Use these controls to select and deselect particles by their ID numbers. Available only at the Particle selection level.

Tip: You can display particle IDs in the viewports by turning on Display operator > Show Particle IDs.

**ID**—Use this to set the ID number of the particle you want to select. You can set only one number at a time.

**Add**—After setting the ID number of a particle to select, click Add to add it to the selection. By default, selecting a particle doesn’t deselect any others.

**Remove**—After setting the ID number of a particle to deselect, click Remove to remove it from the selection.

**Clear Selection**—When on, clicking Add to select a particle deselects all other particles.
System Management rollout

Use these settings to limit the number of particles in the system, and to specify the frequency of updating the system.

Particle Amount group

Upper Limit—The maximum number of particles the system may have. Default=100000. Range=1 to 10000000.

Tip: You can have more than 10,000,000 particles in a single system by using multiple particle sources and wiring them to the same birth event. Note, however, that Particle Flow is limited to sending a maximum of 5,000,000 particles per event to the renderer.

Integration Step group

At each integration step, Particle Flow updates the particle system, applying each active action to particles in its event. A smaller integration step can improve accuracy, at the cost of calculation time. These settings let you apply different integration steps to the particle animation in the viewports and at render time.

Viewport—Set the integration step for animation playback in the viewports. Default=Frame (once per animation frame). Range=1/8 Frame to Frame.

Render—Set the integration step at render time. Default=Half Frame (twice per animation frame). Range=1 Tick to Frame.

There are 4,800 ticks in a second; thus, at the NTSC video rate of 30 frames per second, there are 160 ticks per frame.

Script rollout

This rollout lets you apply a script to the particle system at each integration step, as well as after the last integration step of each frame you view. Use an Every Step Update script to set up history-dependent properties, and a Final Step Update script to set up history-independent properties.

Every Step Update group

The Every Step Update script is evaluated at the end of each integration step, after all actions in the particle system are evaluated, and all particles are finally in their respective events. When, for example, you are setting up Material ID according to a particle index, it is important to be sure that particles are not about to jump to another event.

When you set up history-dependent properties, such as speed, it is important to do that at every
integration step, because otherwise the final position would be quite different.

**Enable Script**—Turn on to cause a script in memory to be executed at each integration step. You can modify this script by clicking the Edit button, or load and use a script file with the remaining controls in this group.

The default script modifies particle speed and direction, causing particles to follow a wavy path.

**Edit**—Click this button to open a text-editor window with the current script.

When Use Script File is off, this is the default Every Step Update script (`3dsmax\scripts\particleflow\example-everystepupdate.ms`). When Use Script File is on, this is the loaded script, if you’ve loaded one. If you haven’t, clicking Edit displays the Open dialog.

**Use Script File**—When on, you can load a script file by clicking the button below.

**[button]**—Click this button to display an Open dialog that lets you specify a script file to load from disk. After you load a script, the name of script file appears on the button.

**Final Step Update group**

The Final Step Update script is executed after the last integration step has been completed for each frame that you view (or render). For example, if you play the animation in the viewport with Real Time turned off, Particle Flow runs this script at each frame, immediately before the particle system is rendered to the viewport. However, if you simply jump to a different frame, the script is run once only, so if the script assumes a certain history, you might get unexpected results.

For this reason, it’s best to use the Final Step Update script to modify history-independent properties. For example, if no operators in the system depend on the material indices, you could use it to modify the material index. In this case there’s no need to set those indices in every intermediate integration step. Also, you can set up a position channel in the Final Step Update script if you know the analytical expression for the position.

**Enable Script**—Turn on to cause a script in memory to be executed after the final integration step. You can modify this script by clicking the Edit button, or load and use a script file with the remaining controls in this group.

The default script modifies particle speed and direction, causing particles to follow a bulb-shaped path.

**Edit**—Click this button to open a text-editor window with the current script.

When Use Script File is off, this is the default Final Step Update script (`3dsmax\scripts\particleflow\example-finalstepupdate.ms`). When Use Script File is on, this is the loaded script, if you’ve loaded one. If you haven’t, clicking Edit displays the Open dialog.

**Use Script File**—When on, you can load a script file by clicking the button below.

**[button]**—Click this button to display an Open dialog that lets you specify a script file to load from disk. After you load a script, the name of script file appears on the button.

### Particle Flow Keyboard Shortcuts

To use Particle Flow keyboard shortcuts, the Keyboard Shortcut Override Toggle on the main toolbar must be turned on.

To view and customize these shortcuts, open the Customize User Interface dialog from the Customize menu, and then, from the Group drop-down menu, choose Particle Flow.
Actions

The Particle Flow components for creating particle systems are known collectively as actions. These are subdivided into three main categories:

- **Operators** (page 2–142)
- **Flows** (page 2–208)
- **Tests** (page 2–210)

### Action Time Frames

Most actions in Particle Flow operate on particles in either of two time frames: once, when the particle first enters the event, or on a continuous basis, potentially changing particle behavior at each integration step. Some actions can work only in one time frame, while others can work on an instantaneous or continuous basis, depending on their settings. The tables below list each action with its time frame.

### Operators

n/a = not applicable
Tests
Most tests in Particle Flow function only as tests. At each integration step, they check each particle for the specified conditions, and then return the test result: True or False. So, as tests, they work on a continuous basis. For example, Age Test checks each particle’s age at every integration step, because particles might not reach the specified age until remaining in the event for a while, and also because another action in the event might change or reset particle age.

The principal exceptions to this are the Split tests, which test each particle only when it first enters the event. That is, a Split test splits the particle stream only once for each particle that enters the event. Any particles that remain in the event are not subject again to being split off from the stream by the same test. Also, the Send Out test performs no test, but simply moves particles along to the next event.

Some tests also function as operators, in that they directly affect particle behavior. These are the ones listed here, and the specified time frame is related to the operator functionality, not the test.

Operators
The operator is the basic element of the particle system; you combine operators into events to specify the particles’ characteristics over a given period of time. Operators let you describe particle speed and direction, shape, appearance, and more.

The operators reside in two groups in the Particle View depot, and within each group appear in alphabetical order. Each operator’s icon has a blue background, except for the Birth operators, which have a green background. The first group contains operators that directly affect particle behavior, such as transformation.

The second group, found at the end of the depot listing, contains four operators that serve more of a utility function: Cache, for optimizing particle-system playback; Display, for determining how particles appear in the viewports; Notes, for adding comments; and Render, for specifying render-time characteristics.

The primary operators in Particle Flow are:

- Birth Operator (page 2–143)
- Birth Script Operator (page 2–145)
- Delete Operator (page 2–146)
- Force Operator (page 2–204)
- Keep Apart Operator (page 2–172)
- Mapping Operator (page 2–195)
- Material Dynamic Operator (page 2–191)
Birth and Death

Birth Operator

*Particle View (page 2–125)* > Click Birth in an event or add a Birth operator to the particle system and then select it.

The Birth operator enables creation of particles within the Particle Flow system using a set of simple parameters. In general, use Birth as the first operator in any event connected directly to a *global event* (page 3–949); this is called the *birth event* (page 3–916).

You can specify a total number of particles, or a rate of particles born per second. You can also tell the system when to begin emitting particles, and when to stop.

**Note:** The Birth operator must always come at the beginning of a particle stream; the system doesn’t let you position it elsewhere. You can place a Birth operator in an isolated event, but you can’t then wire that event in series with a stream that already uses a Birth operator. However, you can wire multiple Birth operators, each in its own event, into a particle stream with an existing Birth operator, *in parallel*. The following procedure illustrates this. If you need to create particles midstream, use the *Spawn Test* (page 2–230) or *Collision Spawn Test* (page 2–215) test.

**See also**

*Birth Script Operator* (page 2–145)

**Procedure**

To use the Birth operator:

This procedure demonstrates the impossibility of using multiple Birth operators in series, and shows how to use multiple Birth operators in parallel.
1. Start or reset the software, and add a new PF Source object to the scene.

2. Press 6 to open Particle View.
   The default particle system contains a Birth operator as the first action in the birth event.

3. Try to drag the Birth operator elsewhere in Event 01.
   You can't. As you drag over the different actions in Event 01, a red line appears at the top of the event, showing that the Birth operator will be placed here, no matter where you release the mouse button.

4. Try to drag a new Birth operator from the depot to Event 01.
   As in the previous step, the only place you can drop the Birth operator is at the top of the event, replacing the existing Birth operator.

5. From the depot, drag the Birth operator to an empty area in the event display.
   Particle Flow creates a new birth event, Event 02, containing the Birth operator and a Display operator.

6. Wire the output of the global event, PF Source 01, to the event input of Event 02.
   Each birth event must be associated with a global event to be able to generate particles.

7. From the depot, add a Send Out test at the end of both Event 01 and Event 02.

8. Try to wire the test output of Event 02 to the event input of Event 01.
   Particle Flow doesn’t let you, because this would result in two Birth operators in series.

9. Try to wire the test output of Event 01 to the event input of Event 02.
   Again, Particle Flow doesn’t let you, because this would result in two Birth operators in series.

10. Drag a Speed operator to an empty area of the event display.
    Particle Flow creates a new event, Event 03.

11. Wire the test output of Event 01 to the event input of Event 03.

12. Wire the test output of Event 02 to the event input of Event 03.
    There’s no problem wiring the two birth events to a single, third event. The birth events exist in the particle stream in parallel, each generating particles independently and then feeding its particle stream into a common event, where the two streams are combined.
    If the second birth event had its own global event, you could, at any point further downstream, separate the streams back out according to their origin using the Split Source test (page 2–236). To do this, delete the wire from PF Source 01 to Event 02, add an Empty Flow (page 2–209) to the system, and then wire it to Event 02.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Emit Start**—The frame number at which the operator begins emitting particles.

**Emit Stop**—The frame number at which the operator stops emitting particles.
Note: The Emit Start and Emit Stop values are tied to the system frame rate. If you change the frame rate, Particle Flow automatically adjusts the Emit values accordingly. For example, if you set Emit Start to 120 and Emit Stop to 300 using the default NTSC frame rate (30 fps), and then switch to PAL (25 fps) using the Time Configuration dialog, you’ve reduced the frame rate to 5/6 of the original value. Thus, Particle Flow automatically uses the same ratio to adjust the Emit settings, resulting in an Emit Start value of 100 and an Emit Stop value of 250. This allows the particle system to retain the timing you specify, no matter which frame rate you use.

With Subframe Sampling off, such adjustments are rounded off to the nearest integer frame number. With Subframe Sampling on, fractional frame values that result from such adjustments will be used, but not displayed.

**Amount**—To specify the total number of particles emitted by the operator, choose Amount, and then set the quantity of particles.

Using the Amount option, the first particle is always emitted at the Emit Start frame, and the last particle is always emitted at the Emit Stop frame. Particles emitted between these endpoints appear at equal intervals within the emission period. For example, if you set Amount to 3, the second particle is emitted halfway through the emission period.

To determine the number of particles emitted per frame when using Amount, divide the Amount value by the number of emission frames (Emit Stop-Emit Start+1).

**Rate**—To specify the number of particles emitted *per second*, choose Rate, and then set the value. The operator emits this number of particles per second starting at the Emit Start frame and ending at the Emit Stop frame.

If you specify a birth rate value that isn’t an integer multiple of the system frames-per-second value (set in the Time Configuration dialog), Particle Flow uses interpolation to determine when to emit particles. For example, if you use the system default rate of 30 frames per second, and set the birth rate to 4, the system would emit each particle at intervals of seven or eight frames if Subframe Sampling is off, or at intervals of 7.5 frames if Subframe Sampling is on.

**Subframe Sampling**—Turning this on helps avoid particle “puffing” by emitting particles at a much higher subframe resolution (that is, throughout each frame), rather than using the relatively coarse frame resolution. Default=on.

“Puffing” is the effect of emitting separate “puff s” or clusters of particles, rather than a continuous stream. This effect is especially noticeable when the emitter is animated.

Turn off Subframe Sampling to cause particles to be emitted exactly at frame times. This makes it easier to sort particles by their age later.

**Birth Script Operator**

![Particle View (page 2–125) > Click Birth Script in an event or add a Birth Script operator to the particle system and then select it.](image)

The Birth Script operator enables creation of particles within the Particle Flow system using a MAXScript script. The script can use any program functionality available to MAXScript.
Chapter 11: Space Warps and Particle Systems

The default script (3dsmax\scripts\particleflow\example-scriptbirth.ms) emits particles for 100 frames in a wavy, circular path. To see this, turn off or delete any Speed and Position operators in the event.

See also
Birth Operator (page 2–143)

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

Edit Script—Click this button to open the current script in a MAXScript Editor window.

For detailed information about the MAXScript utility, open the MAXScript Reference, available from Help menu > MAXScript Reference.

Emit Start—The frame number at which the operator begins emitting particles.

Uniqueness group

The Uniqueness setting provides a randomization seed that the script can use or ignore.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

Delete Operator

Particle View (page 2–125) > Click Delete in an event or add a Delete operator to the particle system and then select it.

Use the Delete operator to remove particles from the particle system. By default, particles live “forever,” that is, for the duration of the animation. The Delete operator lets you give them a finite life span. This is useful for eliminating particles once they’ve served their purpose in the animation.

The Delete operator is also necessary when using the Particle Age map, which, when incorporated into the Material Dynamic operator, applies different materials to particles depending on their age. Because the map works on the basis of a percentage of the particle’s life span, you need to use a Delete operator to define the particles’ maximum age. For an example of usage, see Material Dynamic operator (page 2–191).

Interface

The user interface appears in the Parameters panel, on the right side of the Particle View dialog.

Remove group

Choose whether to delete all particles, selected particles, or particles past a specific age.
The Uniqueness setting enables randomization of maximum particle age using the By Particle Age > Variation setting.

**All Particles**—Deletes all particles in the event immediately.

**Selected Particles Only**—Deletes particles selected at the Particle sub-object level in the event immediately. See *Selection rollout (page 2–138).*

**By Particle Age**—Deletes particles in the event after they’ve existed for a specific length of time, with an optional random variation. Choosing this makes the Life Span and Variation settings available.

**Life Span**—The number of frames of life allowed to the particles. After this period, they’re deleted. Default=60.

**Variation**—The maximum amount by which Life Span may vary. To get each particle’s actual life span, this value is multiplied by a random number between -1.0 and 1.0, and then added to Life Span. Default=10.

**Uniqueness group**

The Uniqueness setting enables randomization of maximum particle age using the By Particle Age > Variation setting.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Transforms**

**Position Icon Operator**

By default, particles are born, or emitted, from the Particle Flow icon. This topic uses the term *emitter* to refer to this icon. Use the Position Icon operator to control the initial placement of particles on the emitter. You can set the emitter to emit particles from its surface, volume, edges, vertices, or center. And, if you animate the emitter, you can cause its motion to be imparted to the particles it emits.

Alternatively, you can use Position Object (page 2–148) to emit particles from any other object.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Lock On Emitter**—When on, causes all particles to remain at their initial positions on the emitter. In
effect, they’re “glued” to the emitter. When off, each particle’s birth position is determined by the emitter’s current location. Default=off.

Inherit Emitter Movement—When on, the software sets each particle’s rate and direction of motion to that of the emitter at the time of birth. When off, the emitter movement doesn’t affect that of the particles. Available only when Lock On Emitter is off. Default=off.

Note: If a Speed operator exists later in the event, it overrides any motion imparted by Inherit Emitter Movement.

Multiplier—Determines, as a percentage, the extent to which particles inherit the emitter’s motion. Available only when Inherit Emitter Movement is on. Default=100.

To have the particles move half as fast as the emitter, set Multiplier to 50. To have them move the same speed, use the default setting of 100. To make the particles move twice as fast as the emitter, set Multiplier to 200.

Location group

The Location drop-down list lets you specify where on the emitter the particles appear. You can create a variety of emission behaviors by varying the icon type, Location setting, and direction of emission. Default=Volume.

- Pivot—Emits particles from the center of the icon.
- Vertices—For the Box and Rectangle icon types, emits particles from the corners of the icon. For the Sphere icon type, emits particles from the six intersections of the three circles that define the sphere. For the Circle icon type, emits particles from the center.
- Edges—Emits particles from random points along the edges of the icon.
- Surface—Emits particles from random points on the surface of the icon.
- Volume—Emits particles from random points within the volume of the icon.

Distinct Points Only—Limits emission to a specific number of points (see Total, below) on the specified Location type.

Emission points are still randomized; change the Uniqueness setting to alter these.

Total—Sets the number of emission points. Available only when Distinct Points Only is on. Default=10.

Subframe Sampling—When on, the operator acquires animation of the emitter icon on a tick basis (every 1/4800th of a second) rather than a frame basis. This provides greater precision in allowing the particle positions to follow animation of the emitter icon. Default=off.

Uniqueness group

The Uniqueness setting lets you alter the randomization of emission points.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

Position Object Operator

By default, particles are born, or emitted, from the Particle Flow icon. The Position Object operator lets you emit particles from any other object or objects in the scene instead. This topic uses the term emitter to refer to an object or objects used to emit particles with this operator. For example, use it to create a meteor’s fiery trail.
Use the Position Object settings to control the initial placement of particles on the emitter. You can set the emitter to emit particles from its surface, volume, edges, vertices, or pivot, or from a sub-object selection. You can also control particle emission with a material applied to the object.

Alternatively, you can use the Position Icon operator (page 2–147) to emit particles from the Particle Flow icon.

Note: Typically, you would use Position Object in a birth event, so the particles appear initially at the emitter object(s). If you use it in a non-birth event, the particles jump to the designated emitter(s) upon entering the event. This could be useful for a teleportation effect.

Tip: The default speed operator, Speed (page 2–159), typically uses the Particle Flow icon to control the direction of the particle flow, so if the emitter object(s) and the icon aren’t coincident and aligned, you might get unexpected results. For better control over the direction of particle movement when using Position Object, use the Speed By Surface operator (page 2–167) instead and designate as Surface Geometry the same object(s) as with Position Object.

Procedure

To use Position Object:

1. Create a Particle Flow system and one or more mesh objects to use as emitters. Animate the emitter objects and set particle system parameters as necessary.

2. In Particle View, add a Position Object operator to the birth event, replacing the Position Icon operator if one exists. Click the operator to display its parameters.

3. In the Emitter Objects group, click Add, and then select an object to serve as the emitter. Alternatively, click By List and then use the Select Emitter Objects dialog to designate one or more objects as emitters.

4. Use the Location drop-down list to choose where the particles should appear on the emitter: surface, vertices, and so forth.

5. Set other options as necessary. For example, if you want the particles to use the same motion as the emitter at the time of emission, turn on Inherit Emitter Movement. Or if you’re using an emitter object whose shape is animated, turn on Animated Shape.
Interface

Lock On Emitter—When on, causes all particles to remain at their initial positions on the emitter. In effect, they’re “glued” to the emitter. When off, each particle’s birth position is determined by the emitter’s current location. Default=off.

Inherit Emitter Movement—When on, the software sets each particle’s speed and direction of motion to those of the emitter at the time of birth. When off, the emitter movement doesn’t affect that of the particles. Available only when Lock On Emitter is off. Default=off.

Note: If a Speed operator exists later in the event, it overrides any motion imparted by Inherit Emitter Movement.

Multiplier—Determines, as a percentage, the extent to which particles inherit the emitter’s motion. Available only when Inherit Emitter Movement is on. Default=100.

To have the particles move half as fast as the emitter, set Multiplier to 50. To have them move the same speed, use the default setting of 100. To make the particles move twice as fast as the emitter, set Multiplier to 200.

Variation—Determines, as a percentage, the extent to which inherited emitter motion can vary per particle. To determine the final multiplier for each particle, the Variation value is multiplied by a random number between -1.0 and 1.0, and then added to the Multiplier value. Default=0.

Emitter Objects group

Use these controls to assign objects to be used as particle emitters. The list in this group shows the objects, or reference geometry, that the operator uses as emitters.

If you don’t assign any objects, Particle Flow uses the world origin (0,0,0) as the emitter source.

With more than one emitter object, the division of particles among the objects depends on which option you choose for Location. If you set Location to Pivot, then each object has one emission point and each object emits the same number of particles.
(total number of particles/number of objects). But if you set Location to any other option, each object emits a number of particles proportionate to the number of available emission points per object. For instance, if you set Location to Volume, then a larger object will emit more particles than a smaller one. Similarly, with Location set to Vertices, an object with 100 vertices will emit twice as many particles as an object with 50.

If you delete from the scene an object designated as an emitter, its entry in the list is replaced with “<deleted>”.

Use the Add and Remove buttons to edit this list.

Add—Add an object to the list. Click Add, and then click an object in the viewport.

By List—Add multiple objects to the list. Click By List to open the Select Emitter Objects dialog. This works just like the Select Objects dialog (page 1–78); highlight the objects to use as emitters, and then click the Select button.

Remove—Removes an object from the list. Highlight the object in the list, and then click Remove.

Animated Shape—Turn on to allow particles to emit from the surface of an object whose form is animated by morphing or with modifiers.

Subframe Sampling—When on, the operator acquires animation of the emitter shape on a tick basis (every 1/4800th of a second) rather than a frame basis. This provides greater precision in allowing the particle positions to follow animation of the emitter object’s form.

Location group
The Location drop-down list lets you specify where on each emitter the particles appear. This choice applies to all emitter objects. Default=Surface.

The Selected Vertices/Edges/Faces options in this list let you emit particles from a specific part of the emitter object by using an existing sub-object selection. To create this selection, first convert the object to an editable mesh or poly, or apply a Mesh Select or Poly Select modifier (or equivalent), select the sub-objects that are to emit particles, and then choose the corresponding Location option. If the software doesn’t find a sub-object selection, it uses all sub-objects of the indicated type.

Pivot—Emits particles from the original position of the emitter object’s pivot. Moving the pivot does not affect this option.

Vertices—Emits particles from randomly selected vertices of the emitter objects.

Edges—Emits particles from random points along the edge sub-objects of the emitter objects.

Surface—Emits particles from random points on the surface of the icon.

Volume—Emits particles from random points within the volume of the icon.

Selected Vertices—Emits particles from the current vertex sub-object selection.

Selected Edges—Emits particles from the current edge sub-object selection.

Selected Faces—Emits particles from the current face or polygon sub-object selection.

You can modify the Location choice with any combination of the following:

Surface Offset—Lets you specify a range of distances from the object surface for particle placement.

Surface Offset is unavailable when Location is set to Pivot or Volume. Use the Min and Max parameters to set the range.

Note: Negative values offset the particles below the surface.

Min/Max—When Surface Offset is on, these let you specify the range of offset distances from the
object surface. The Min value cannot exceed the Max value, and vice-versa. If you try to raise Min above Max, or lower Max below Min, both values change equally.

**Density by Material**—Varies emission over the emitter surface based on properties of the material applied to the emitter. For example, if the object is assigned a black-and-white checkered diffuse map and you choose the Grayscale option, particles are emitted only from the white checks.

**Important:** For material-influenced emission to appear properly in the viewports, two conditions are required:

- At least one viewport must be set to a shaded display mode.
- The material or map must have Show Map In Viewport turned on in the Material Editor.

The options are as follows:

- **Grayscale**—The software internally converts the material-based coloring (diffuse) to grayscale, and then emits more particles in lighter areas and fewer in darker areas.
- **Opacity**—Particles are more likely to appear on opaque areas than on transparent areas.
- **Grayscale & Opacity**—Combines the two: More particles appear on light, opaque areas than on dark, transparent areas.
- **Red/Green/Blue**—Considers only the specified color channel. The higher its value at any given pixel, the more likely particles are to appear there.

**Use Sub-Material**—When on, uses a sub-material from the Multi/Sub-Object material assigned to the emitter to define density values.

This option allows usage of “invisible” materials for particle placement. If the emitter uses a Multi/Sub-Object material but its geometry doesn’t use the ID that corresponds to one of the sub-materials, the sub-material doesn’t appear. However, the operator can use it to calculate the density of particle placement. The software assumes the material to be applied to the entire object surface.

**Mtl ID**—Specifies the material ID of the sub-material to be used for particle emission.

**Separation**—When on, the software attempts to keep the particles apart by the amount specified in Distance. The likelihood of successfully separating particles depends on the number of particles, the specified distance, and the Attempts Max value.

**Distance**—Specifies the distance, in system units, by which the software should try to keep the particles separate. Default=1.0.

**Distinct Points Only**—Limits emission to a specific number of points (see Total, below) on the specified Location type.

Emission points are still randomized; change the Uniqueness setting to alter these.
Total—Sets the number of emission points. Available only when Distinct Points Only is on. Default=10.

If Location Is Invalid group
Delete Particles—When on, if the software cannot place a particle according to the current option, it deletes the particle. When off, particle placement is undefined; that is, it depends on other variables. Default=off.

If the number of particles is more important than the position on the object, leave this off. However, if exact placement is of higher priority than the number of particles, turn Delete Particles on.

Uniqueness group
The Uniqueness setting enables randomization of placement on the emitters.
Seed—Specifies a randomization value.
New—Calculates a new seed using a randomization formula.

Attempts Max—When using the Separation option, this specifies the maximum number of times Particle Flow will try to set particle positions that maintain the requested distance. If unsuccessful within this number of attempts, particles might be closer together than the requested distance. Also affects placement with Density By Material using either of the Grayscale options.

The Rotation operator lets you set and animate particle orientation during an event, with optional random variation. You can apply orientation in any of five different matrices: two random and three explicit. For some options you can set a degree of random variation or divergence from the specified orientation.

To cause particles to spin, use the Spin operator (page 2–154).

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

Orientation Matrix group
The Orientation Matrix setting includes options that give particles random orientations, or let you specify orientation in any of three different ways. Default=Random 3D.

Random 3D—Gives each particle an arbitrary, random 3D orientation.
Random Horizontal—Gives each particle an arbitrary, random 3D orientation about the Z axis only. Rotation about the X and Y axes doesn’t change (unless Divergence is used), so the particles remain vertical.
World Space—Orientation is specified in the world coordinate space.

Use the X/Y/Z settings to specify the orientation for all particles.
Speed Space—The coordinate space for particle orientation is determined by the particles' direction upon entering the event.

By default, using the Speed operator (page 2–159) > Along Icon Arrow option, particles are aimed straight down when born.

Use the X/Y/Z settings to specify the orientation for all particles.

Speed Space Follow—The coordinate space for particle orientation is determined continually while the particles are in the event. Thus, by default, particles constantly reorient themselves to "aim" in the direction they're traveling.

For example, if you add a Find Target test (page 2–218) to the end of the default Event 01, move the target sideways, and set Rotation to Speed Space Follow, the particles start out pointing straight down, as oriented by the Speed operator, and then gradually reorient themselves to point in the direction they're traveling.

Use the X/Y/Z settings to specify the orientation for all particles. The Divergence setting is unavailable when using Speed Space Follow.

X/Y/Z—Set the basic orientation about the particles' local axes. Unavailable with the Random 3D and Random Horizontal options.

Divergence—Defines the range of variation (in degrees) for particle orientation. The actual deviation is calculated at random within this range. Unavailable with the Random 3D or Speed Space Follow option. Default=0.0.

Restrict Divergence To Axis—When on, lets you use the Divergence Axis controls to set the axis to which divergence will be applied. When off, the software uses a random axis for each particle. Unavailable with the Random 3D or Speed Space Follow option. Default=off.

Divergence Axis—Use the X/Y/Z settings to set the axis to which divergence will be applied. Default=1,0,0. Range=-1.0 to 1.0.

To specify one of the world axes, set the corresponding parameter to any non-zero value, and the others to 0. A negative value flips the axis.

The numeric values come into play when you want to use an axis that's not aligned with the X, Y, or Z axis. In that case, you specify multiple non-zero values whose effect is relative to one another.

For example, if you want the axis to be oriented halfway between the positive X and Y axes, you would set X and Y to the same positive amount. The actual value doesn't matter. Similarly, to set the axis to 30 degrees (1/3 of the angle) from the X axis to the Y axis, you'd set the Y value to twice that of the X value. For example, X=0.2 and Y=0.4, or X=0.5 and Y=1.0.

Uniqueness group

The Uniqueness setting affects the randomization of orientation with the Random 3D and Random Horizontal options, and also Divergence.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

Spin Operator

Particle View (page 2–125) > Click a Spin operator in an event or add a Spin operator to the particle system and then select it.

The Spin operator gives an angular velocity to particles in an event, with optional random variation. Spin is applied once per event per particle, except when using the Speed Space Follow option; however, the settings can be animated.

To simply specify particle orientation, use the Rotation operator (page 2–153).
**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Spin Rate**—The rate of revolution in degrees per second.

**Variation**—The maximum amount, in degrees per second, by which the spin rate can vary. The actual variation is calculated once, at random, for each particle.

**Spin Axis**

The Spin Axis setting includes options that let you apply the spin on a random or specific axis, with optional random variation of the spin axis. Default=Random 3D.

**Random 3D**—Spins each particle about an arbitrary, random 3D axis.

**World Space**—The spin axis is specified in the world coordinate space.

Use the X/Y/Z settings to specify the spin axis.

**Particle Space**—The spin axis is specified in the local coordinate space of each particle.

Use the X/Y/Z settings to specify the spin axis.

**Speed Space**—The coordinate space for particle orientation is determined by the particles’ direction upon entering the event.

The X axis is aligned with the particle direction, while the Z axis is perpendicular to the X axis and is pointed upward with respect to world space as much as possible.

Use the X/Y/Z settings to specify the orientation for all particles.

**Speed Space Follow**—The coordinate space for particle orientation is determined by the particles’ direction throughout the event. Use this option to allow particles that change direction during the event to keep the spin axis aligned with their direction.

The X axis is aligned with the particle direction, while the Z axis is perpendicular to the X axis and is pointed upward with respect to world space as much as possible.

Use the X/Y/Z settings to specify the orientation for all particles.

**X/Y/Z**—Use these to set the spin axis. Unavailable for the Random 3D option. Default=0,0,1. Range=-1.0 to 1.0.

To specify a single axis, set the corresponding parameter to any non-zero value, and the others to 0. A negative value flips the axis, and reverses the direction of rotation. The numeric values come into play when you give more than one axis a non-zero value, in which case their effect is relative to one another. For example, if you want the spin axis to be oriented halfway between the positive X and Y axes, you would set X and Y to the same positive amount. The actual value doesn’t matter. Similarly, to set the spin axis to 30 degrees (1/3 of the angle) from the X axis to the Y axis, you’d set the Y value to twice that of the X value. For example, X=0.2 and Y=0.4, or X=0.5 and Y=1.0.
**Divergence**—Defines the range of variation (in degrees) for spin-axis orientation. The actual deviation is calculated at random within this range. Unavailable for the Random 3D option. Default=0. Range=0 to 180.

**Uniqueness group**

The Uniqueness setting affects the randomization of spin rate variation, spin axis with the Random 3D option, and Divergence with the other options.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Scale Operator**

*Particle View (page 2–125)* > Click a Scale operator in an event or add a Scale operator to the particle system and then select it.

The Scale operator lets you set and animate particle size during an event, with optional random variation. Options for how scaling and animation are applied give this operator a great deal of flexibility.

**Procedure**

**Example: To animate particle scale:**

This procedure gives an overview of animating particles to grow for 30 frames, remain at full size for the next 30 frames, and then shrink for 30 frames. It also gives an option for having the particles pulsate in size during the middle period. To follow this procedure, you should be familiar with the basic usage of Particle Flow and Track View.

1. Set up a default Particle Flow system. Set the Shape operator to Sphere, and set the Display operator to Geometry.
2. Add a Send Out test to Event 01.
3. Add a new Scale operator to the event display, creating a new event. Set the new event’s Display operator to Geometry, and make sure it’s a different color than the one in Event 01.
4. Wire the Send Out test in Event 01 to Event 02.
5. In the Event 02 > Scale operator, set Type to Absolute, and animate the Scale Factor values from 10 to 100 over frames 0 to 30. In the Animation Offset Keying group, set Sync By to Event Duration.
6. Add an Age Test to Event 02. Set it to Event Age, set Test Value to 30, and Variation to 0.

In this event, particles grow from 10 percent of their original size to full size over the first 30 frames of their existence, which is the same as their duration in the event. At that point, they’ll be eligible to move to the next event.

7. Use a new Scale operator to create a new event, Event 03. Set the new event’s Display operator to Geometry, and make sure it’s a different color than the others.
8. Wire the Age Test in Event 02 to Event 03.
9. In the Event 03 > Scale operator, Set Type to Absolute, and in the Animation Offset Keying group, set Sync By to Event Duration.
10. Copy and paste the Age Test as an instance from Event 02 to Event 03.

Particles in Event 03 remain at full scale for 30 frames, and then move on to the next event.

11. Use a new Scale operator to create a new event: Event 04. Set the new event’s Display operator to Geometry, and make sure it’s a different color than the others.
12. Wire the Age Test in Event 03 to Event 04.
13. In the Event 04 > Scale operator, set Type to Absolute, and animate the Scale Factor values from 100 to 10 over frames 0 to 30. In the Animation Offset Keying group, set Sync By to Event Duration.
14. Copy and paste the Age Test as an instance from Event 03 to Event 04.
In this event, particles shrink from full size to 10 percent of their original size over 30 frames.

15. Play the animation.
Next, you'll use a Noise controller to cause the particles in Event 03 to pulsate in size.

16. Add a second Scale operator to Event 03, below the existing Scale operator. Set it to Relative Successive, and set Sync By to Event Duration.
The name of this operator should be Scale 04.

17. In Particle view, right-click the Scale Factor X % parameter field on the Scale 04 rollout, and choose Show In Track View.
The Curve Editor opens with the X Scale Factor parameter highlighted.

18. Right-click the X Scale Factor item and choose Assign Controller from the menu.

19. In the Assign Float Controller dialog, double-click Noise Float.
The Noise Controller dialog opens.

20. Set Strength to 200, and to the right of Strength, turn on the >0 check box.

21. Copy this controller, and then paste it as instances to Y Scale Factor and Z Scale Factor.
Although the Scale operator defaults to constraining all scale factors to the same value, thus scaling particles uniformly, changing controllers in Track View works on a per-parameter basis.

22. Play the animation.
This time, the particles grow in size for 30 frames, then pulsate in size for the next 30 frames, and then shrink from the size at the end of Event 03 to 10 percent of that over the next 30 frames.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Type**
The scaling Type setting includes options that let you scale particles once in an event or repeatedly, and apply scaling as an absolute or relative factor. Default=Overwrite Once.

- **Overwrite Once**—Sets the scale one time only as an absolute percentage value, disregarding any previous scaling.

To produce a range of different birth sizes, and specify the scaling explicitly, use Overwrite Once with animated scale factors.

- **Inherit Once**—Sets the scale one time only as a percentage of existing scaling. The existing scaling
should be specified with a previous Scale operator, the Scale setting in the Shape operator (page 2–176), or a Shape Instance operator (page 2–178).

For instance, if you previously used Scale with Overwrite Once to scale particles' birth size within a range, and then want to scale them to half their previous size, use Inherit Once and set Scale Factor to 50%.

**Absolute**—Sets the scale continuously, while the particle is in the event, as an absolute percentage value, disregarding any previous scaling.

Use Absolute if you want to animate the particles' scale explicitly.

**Relative First**—Sets the scale continuously, while the particle is in the event, as a percentage of existing scaling. The existing scaling should be specified with a previous Scale operator, or a Shape Instance.

Use Relative First when you want to scale the particles relative to the scaling at which they enter the event, and optionally animate the scaling, or before a Relative Successive operator.

**Relative Successive**—Scales the particles continuously, relative to scaling set earlier in the same event.

Note: Always precede Relative Successive in the same event with an operator that modifies the scale channel all the time, such as a Scale operator set to Absolute or Relative First, or a Shape Instance operator with the Scale check box turned on (it's on by default).

**Scale Factor group**

The operator performs scaling on each particle's local axes. It can scale particles on a single axis or on any combination of axes.

**X/Y/Z**—Sets the scaling as a percentage of the particle's current size. To scale uniformly, turn on Constrain Proportions, and then change any axis setting. Range=0 to 10000000. Default=100.

**Constrain Proportions**—When on, retains the current ratio of scale factor settings, so that changing any axis setting changes all of them. Default=on.

**Scale Variation group**

**X/Y/Z**—Sets the scaling variation as a percentage of the particle's previous size. To scale uniformly, turn on Constrain Proportions, and then change any axis setting. Range=0 to 100. Default=0.

**Constrain Proportions**—When on, retains the current ratio of scale variation settings, so that changing any axis setting changes all of them. Default=on.

**Bias**—Lets you choose how to distribute the scaling variation within the specified range or ranges. Default=None.

- **None**—No bias; scaling variation is distributed equally through the range.
- **Centered**—Scaling variation is concentrated near the middle of the range; that is, at 0.0%. With this choice, scaling will occur more frequently with low percentage values than with ones near the values you set. In other words, most scaling variants will be close to the specified scaling value.
- **Towards Minimum**—Scaling variation is concentrated near the lower end of the range (base-variation); that is, most scaling variants will be smaller than the scaling value.
- **Towards Maximum**—Scaling variation is concentrated near the upper end of the range (base+variation); that is, most scaling variants will be larger than the scaling value.

**Animation Offset Keying group**

If you animate the Scale Factor or the Scale Variation settings or both, the software can begin applying this animation to all particles as of the start frame of the animation or the first frame of
the current event, or to each particle based on its age. For instance, if you set Sync By to Particle Age, and set Scale Factor keys at frames 0 and 30, then the software will animate the scaling factor for each particle between its birth and its 30th frame of existence, if the particle is in the scaling event or a prior event. Following this example, any particle that has already reached its 30th frame of existence before reaching the event will enter the event fully scaled. That is, the software will apply the Scale Factor value that you set at frame 30 to each particle aged 30 or above at the moment it enters the scaling event. However, any particle that leaves the scaling event before reaching age 30 will stop scaling as of its exit frame. In other words, with respect to particles in other events, animation of action parameters is retroactive, but not post-active.

Alternatively, if you set Sync By to Absolute Time, the scaling is animated from frame 0 to frame 30 of the animation, regardless of particle age, and even if no particles are in the event at that time. Or, if you set Sync By to Event Duration, the scaling animation is applied to each particle as of the time that it enters the event.

Note: With the Overwrite Once and Inherit Once scaling types, scaling always occurs with respect to the entire animation; that is, in Absolute Time mode. Thus, when either of those scaling types is in effect, the Sync By setting is unavailable. Also, if you animate Scale Factor or Scale Variation when using Overwrite Once or Inherit Once, it doesn’t cause scaling animation in the particles, but rather applies one-time scaling to particles born during that period. For instance, if you animate Scale Factor on all three axes from 100% to 200% over frames 0 to 30, particles born at frame 0 are normal size, particles born at frame 15 are one-and-one-half times normal size, and particles born at frame 30 (and thereafter) are twice normal size.

Sync By—Choose the time frame for applying animated parameters:
- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
- **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.

Uniqueness group

The Uniqueness setting affects the randomization of scale variation.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

---

**Speed**

**Speed Operator**

[Particle View (page 2–125) > Click Speed in an event or add a Speed operator to the particle system and then select it.]

This is the default Speed operator, which appears in the first event when you create a new Particle Flow icon. It provides basic controls over particle speed and direction.

Directional controls provided by the Speed operator are based on the position and orientation of the Particle Flow icon. For best results when using other objects as emitters, use the **Speed By Surface Operator (page 2–167)** operator instead.
See also

*Speed By Icon Operator (page 2–162)*
*Keep Apart Operator (page 2–172)*

Procedure

**Example: To change particles’ speed:**

The Speed operator works on an instantaneous basis: It sets each particle’s speed once only, when it enters the event. Even if you animate the Speed value, each particle moves at a constant rate of speed, defined by the value at the time it enters the event. This procedure demonstrates a trick you can use to change particle speed with an animated Speed value, thanks to Particle Flow’s looping ability.

1. Create a default particle system, and position it at the top of the Perspective viewport.
2. Play the animation.
   The particles fall downward at the default rate: 300 units per second.
3. Add a Send Out test at the bottom of Event 01.
4. Add a Speed operator to an empty area of the event display.
   This creates a new event.
5. Turn on Auto Key, and move the time slider to frame 30.
6. In Particle View, click the new Speed 02 operator, and then in the Particle View parameters panel, set Speed to 0.
   This animates the Speed value from 300 at frame 0 to 0 at frame 30.
7. Turn off Auto Key.
8. Wire the Send Out test in Event 01 to Event 02.
9. Play the animation.
   The particles born later move slower, but all still move at a constant rate of speed.

10. Add a Send Out test at the end of Event 02.
11. Create a new event using an Age Test. Click the Age Test to display its parameters, and then set the following:
   - Event Age
   - Test Value=1
   - Variation=0
12. Wire the Send Out test in Event 02 to Event 03.
13. Wire the Age Test in Event 03 to Event 02.
14. Play the animation.
   All the particles slow down simultaneously and eventually come to a stop.

Here’s how it works: As each particle enters Event 02, its speed is set to the current Speed value in the Speed operator. Particle Flow then sends the particle immediately to Event 03, where it sits for one frame. Event 03 then returns the particle to Event 02, whose Speed value is now lower. Particle Flow perceives the returned particle as newly entering the event, so it changes its speed to the current Speed value. Thus, the particles continually return to Event 02 one frame later than before, and are assigned a progressively lower speed.

If you wanted the particles to do something else after they stop, you could add a Speed Test to Event 02, above the Send Out test, set Test True If Particle Value to Is Less Than Test Value, and set Test Value to a very low value, such as 0.01. Then wire the Speed Test to a different event.
The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Speed**—The particle speed in system units per second. Default=300.

A positive Speed value moves the particles in the direction determined by the Direction setting; a negative Speed value moves the particles in the opposite direction.

Note: Speed sets each particle’s speed once only: when the particle enters the event (or is born, in the case of a birth event). If you animate the Speed value, particle speed does not vary: rather, each particle is given a constant speed equal to the current Speed value when it enters the event.

**Variation**—The amount by which particle speed can vary, in system units per second. Default=0.0.

To obtain each particle’s speed, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Speed value. For example, if Speed=300 and Variation=100, then each particle’s speed would be between 200 and 400.

**Direction group**

The Direction drop-down list lets you specify which way the particles go after they’re born.

Default=Along Icon Arrow. In most cases, the actual direction also depends on the icon orientation. The primary exception is when Position > Location is set to Pivot.

Particle movement is always in a straight line unless influenced by other factors.

**Along Icon Arrow**—Particles move parallel to the icon arrow. Rotate the icon to change the direction.

**Icon Center Out**—Each particle moves along an imaginary line drawn between the particle’s location and the icon center.

With the flat icon types (Rectangle and Circle), this results in all the particles moving in one plane, unless you increase Divergence above 0.0. With icons that have height (Box and Sphere), the particles move outward in three dimensions.

Particles at the center, as is the case when the Position operator’s Location parameter is set to Pivot, arbitrarily move along the world X axis.

**Icon Arrow Out**—Each particle moves along an imaginary line drawn between the particle’s location and the icon arrow. The line is perpendicular to the icon arrow, which is considered an infinite line for this purpose.

With the flat icon types (Rectangle and Circle), this results in all the particles moving in one plane, unless you increase Divergence above 0.0. With icons that have height (Box and Sphere), the particles move outward in a cylindrical formation.

**Random 3D**—Particles move in all directions. This option is affected by the Uniqueness setting.

**Random Horizontal**—Each particle moves in a random horizontal direction; that is, parallel to the world XY plane. This option is affected by the Uniqueness setting.

**Inherit Previous**—Uses the current direction of motion.
If you choose Inherit Previous but no direction was previously specified, the speed and direction are undefined; the particles don’t move.

**Reverse**—When on, the direction is reversed. Default=off.

Using Reverse is the equivalent of multiplying the Speed value by -1. This option is unavailable if Random 3D or Random Horizontal is chosen.

**Divergence**—When on, spreads out the particle stream. Use the numeric setting to define the extent of the divergence, in degrees. Range=0 to 180. Default=0. The value can be animated.

This option is unavailable if Random 3D is chosen.

Tip: For a fountain-like spray, set Position > Location to Pivot, set Direction to Along Icon Arrow, set Divergence to the desired angle, and rotate the icon so its arrow points upward.

**Uniqueness group**

The Uniqueness setting enables randomization of speed variation, and randomization of direction with the Random 3D and Random Horizontal options.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Speed By Icon Operator**

When you add a Speed By Icon operator to the particle system in Particle View (page 2–125), the Speed By Icon operator icon appears in the scene at the world origin (0,0,0). When animated, the operator icon’s motion is imparted to the particles. If you delete the icon, the software also deletes the operator.

**Warning:** If you delete a Speed By Icon operator icon in the viewport, you also delete the corresponding operator in the Particle Flow system.

**See also**

* Speed Operator (page 2–159)
* Speed By Surface Operator (page 2–167)
* Keep Apart Operator (page 2–172)

**Procedures**

**To use the Speed By Icon operator:**

1. Add a Speed By Icon operator to an event. Be sure to add it after any existing Speed operators in the event. Alternatively, delete or turn off any existing Speed operators.

   The Speed By Icon operator icon appears at the world origin (0,0,0).

2. Animate the icon as you would any object. You can do this manually, or with a controller such
as Path Constraint. See the following procedure for an example of this.

The particles' motion is now under the influence of the animated icon.

3. Set the Speed By Icon parameters. With the icon selected, you can do this in the Modify panel.

In general, the default Icon Animation > Sync By setting, Event Duration, works best. It causes the icon animation to be applied to the particles within the time frame of the event containing the Speed By Icon operator.

**Example: To send particles along a path:**

1. Reset the software, and then add a Particle Flow system in the Perspective viewport.

2. On the Create panel, choose Shapes > Splines > Helix, and then, in the Perspective viewport, at the center of the grid, create a helix shape. Then, on the Parameters rollout, set the following:
   - Radius 1 = 100
   - Radius 2 = 20
   - Height = 20
   - Turns = 3
   - Bias = 0

   This will serve as the particle path.

3. Move and rotate the Particle Flow source icon so that it’s at the start of the helical path, and aimed along the path, as shown. Get the base of the arrow as close as possible to the start of the path.

4. Open Particle View (press 6).

5. In Event 01, click the Position Icon operator and set Location to Pivot.

   This causes the particles to be emitted in a thin stream.

6. Insert a Speed By Icon operator at the end of Event 01.

   The operator icon appears at the world origin.

7. Select the operator icon, and then, from the Animation menu, choose Position Controllers > Path Constraint (page 2–398).

   When you move the mouse cursor into the viewport, a rubber-band line joins the cursor to the icon.

8. Select the Helix object.

   The command panel switches to the Motion tab, and the controls indicate that the software has applied a Position List controller to the icon, with the listed controllers being a Position XYZ and a Path Constraint. You can delete the former if you like, but it doesn’t make any difference for the purposes of this procedure.

9. Close Particle View, and then drag the time slider back and forth between its extents a few times.
Tip: The best way to view the results is from the Top viewport.

The particles follow the path fairly closely, but diverge noticeably at the end of the path, where the turns are tightest. Correcting divergence in tight turns typically requires an increase in the acceleration limit.

The particle stream diverges from the path at its endpoint.

10. Stop at frame 100.

This will let you see the results of changing the Speed By Icon parameters as you make the changes.

11. Open the Modify panel, and, if necessary, select the Speed By Icon operator icon.

The operator parameters appear on the Modify panel. This is the case with any action that uses a unique icon, and lets you adjust the parameters without using Particle View.

12. On the Parameters rollout, use the Accel Limit spinner to slowly increase the value as you observe the changes to the particle path.

As you approach a value of 150, the end of the particle path comes closer and closer to the Helix. You shouldn’t see much change above 150.

The endpoints now coincide.

13. Drag the time slider again.

The particle path remains similar to that of the Helix for the entire duration of the animation. With other setups, you might need to use different values for Influence %, and for paths with tight twists and turns, you might need to increase Accel Limit as well.

You might be wondering why you didn’t simply replace the default Speed operator with the Speed By Icon operator. To see why not, try this:

14. Go to frame 100, open Particle View, and click the Speed 01 operator’s icon to turn it off. Play the animation.

The entire particle path is offset from the Helix, so it’s difficult to tell how closely it follows the latter’s curves.

15. Try adjusting the Speed By Icon’s Accel Limit and Influence % setting to get the particles to follow the helical path more closely.

It’s not easy. You get more reliable results using the Speed operator to set the initial speed, and then Speed By Icon to set the particle path.

To use the Use Icon Orientation option:

The Use Icon Orientation option applies arc-like motion to the particles based on rotation animation of the icon. To best understand how it works, it’s necessary to isolate its influence by eliminating any potentially conflicting factors.
1. Reset the software, and then add a Particle Flow system in the Perspective viewport. Set its position to the world origin: (0,0,0).

2. Open Particle View and click the Birth operator. Set Emit Stop=0.
   This causes all particles to appear at frame 0.

3. Click the Speed operator and press the Delete key to delete it.

4. Drag a Speed By Icon operator from the Depot to the end of Event 01.
   The Speed By Icon operator icon appears at the world origin.

5. Select the Speed By Icon operator icon, and then right-click the icon and choose Rotate from the menu. Go to frame 20, turn on Auto Key, and rotate the icon 180 degrees about the X axis.

6. Turn off Auto Key.

7. Drag the time slider.
   The particles aren’t affected by the icon animation.
   Because the Speed By Icon operator icon is selected, the operator’s parameters appear on the Modify panel.

8. On the Modify panel, turn on Use Icon Orientation. Drag the time slider again.
   This time, the particles move in unison with the icon rotation, as if they were glued to an infinite plane coincident with the icon.

9. Go to frame 10, select the Particle Flow source icon (not the Speed By Icon operator icon), and then right-click the icon and choose Move from the menu. Move the icon straight up, on the Z axis, about 100 units.
   As you drag upward, the particles move away from the icon.

10. Drag the time slider again. This time the particles move in an arc around the icon.

11. Try moving and rotating the two icons, playing the animation each time you make a change. Also set Emit Stop back to 30.
   As you can see, the possibilities with just this simple setup are myriad. In combination with the many other variables and options in Particle Flow, they’re endless.

---

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog. When the icon is selected, the parameters also appear on the Modify panel.

**Accel(eration) Limit**—The maximum amount, in system units per second per second, by which the...
particles’ speed can change in order to match the speed of the operator icon. Default=100.0.

If the operator icon changes speed or direction rapidly, increase this value to let the particles follow it more closely.

Tip: Use a lower Accel Limit value for smooth motion, and a higher value when greater accuracy is needed, such as when the particles should hit a small target. You can animate this setting (use Sync By > Event Duration) to specify different appropriate values, depending on the required results.

**Influence %**—Determines the mix of the previous speed with the speed of the operator icon. Default=100.0. Range=0.0 to 100.0.

At the default value of 100, the speed is controlled only by that of the icon. At 0, the icon speed doesn’t affect particle speed at all. At in-between values, the mix proportion is determined by the Influence % value.

**Speed Variation**—Enables random variation of the particles’ speed, so they don’t all move at exactly the same rate as the icon. Turn this on, and then set the minimum and maximum percentages of variation. Default=off.

Using Speed Variation can help keep the particles from bunching up as they travel along the animation path. Note, however, that each individual particle’s speed doesn’t vary; it travels at a constant speed.

**Min %/Max %**—Set the minimum and maximum percentages, respectively, of particle speed variation. Default=50.0 (Min %), 100.0 (Max %).

For example, if you set Min % to 50 and Max % to 200, the particles will vary in speed between half and two times the speed of the icon.

**Use Icon Orientation**—Applies animation of the icon’s orientation to the particles.

By default, Speed By Icon controls particle motion only by animation of the icon’s position. If you turn on Use Icon Orientation, the software also applies rotation of the icon to the particle motion. In essence, this motion is circular, and its extent depends on the distance between each particle and the icon. Default=off.

The best way to understand how this works is by using it. To try out Use Icon Orientation, see *this procedure* (page 2–164).

**Steer Towards Trajectory**—Particles farther away than the Distance value from the icon are moved directly toward the icon. Default=off.

**Distance**—Sets the distance between the particles and the operator icon beyond which Steer Towards Trajectory takes effect. Default=10.0.

**Parameters Animation group**

If you animate the operator settings, the software can begin applying this animation to all particles as of the start frame of the animation or the first frame of the current event, or to each particle based on its age. For instance, if you set Sync By to Particle Age, and set Speed Variation keys at frames 0 and 30, then the software will animate the speed variation for each particle born while the event is active between its birth and its 30th frame of existence. Alternatively, if you set Sync By to Absolute Time, the speed variation is animated from frame 0 to frame 30 of the animation, even if no particles are in the event at that time. Or, if you set Sync By to Event Duration, the speed variation animation is applied to each particle as of the time that it enters the event. For further information, see *Animation Offset Keying group* (page 2–158).

**Sync By**—Choose the time frame for applying animated parameters:

- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
• **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.

• **Event Duration**—Any keys set for parameters are applied to each particle relative to the frame at which it first enters the event.

**Icon Animation group**
The software can begin applying animation of the Speed By Icon operator icon to all particles as of the start frame of the animation or the first frame of the current event, or to each particle based on its age. For an explanation, see *Animation Offset Keying group* (page 2–158).

**Sync By**—Choose the time frame for applying animation of the icon to the particles:

• **Absolute Time**—Any keys set for icon motion are applied at the actual frames for which they’re set.

• **Particle Age**—Any keys set for icon motion are applied at the corresponding frames of each particle’s existence.

• **Event Duration**—Any keys set for icon motion are applied to each particle relative to the frame at which it first enters the event.

**Icon Size**—Sets the size of the operator icon. This setting is for visibility only; it doesn’t affect particle behavior.

**Uniqueness group**
The Uniqueness setting enables randomization of the speed variation range.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Speed By Surface Operator**

The Speed By Surface operator lets you control particle speed and direction with any object or objects in the scene. This is in contrast to the default *Speed operator* (page 2–159), which uses the Particle Flow icon to control particle speed and direction. Speed By Surface also provides options for controlling speed by materials in the scene, and continuous speed control.

Typically, you use Speed By Surface to assign speed and direction characteristics based on the objects used as emitters with the *Position Object operator* (page 2–148). That is, you assign the same objects as emitters with Position Object and as Surface Geometry objects with Speed By Surface.

**Tip** For greater control over particle motion on the surface, apply a *Speed operator* (page 2–159) before the Speed By Surface operator in the same event. Use the Speed operator to specify particle direction on the surface, and the Speed By Surface operator to adjust the vertical component of the speed vector to follow the contour of the surface.

**See also**

*Speed By Icon Operator* (page 2–162)

*Keep Apart Operator* (page 2–172)

**Procedure**

**Example: To use Speed By Surface:**
The Speed By Surface operator offers a wealth of possibilities for usage. This procedure will lead you through several examples, but you’re encouraged to explore the operator further on your own to learn more about it.

1. Start or reset the software, and add a Particle Flow system. Position the source icon at the
world origin (X/Y/Z=0), and set the icon’s Length and Width values both to 30.

2. Add a Cylinder primitive to the scene. Position it above the source icon: X/Y=0 and Z=30. Set Radius=20 and Height=40.

3. Play the animation, and then stop.
   The particles move downward, using the default starting setup.

4. Open Particle View and add a Speed By Surface operator to the end of Event 01. Click the operator in the event to display its parameters panel in Particle View.

5. In the Surface Geometry group, click Add, and then select the cylinder.

6. Play the animation again, and then stop.
   The particles still move downward.

7. Go to frame 15, so you can see the particles, and then slowly move the cylinder downward along the Z axis, while watching the particles in the Perspective and Front viewports. Stop when the emitter is above the cylinder.
   As the bottom of the cylinder passes below the emitter, more and more particles start moving on the XY plane rather than perpendicular to it. That’s because they eventually become closer to one of the vertical sides of the cylinder, rather than the bottom, at which point they move perpendicular to the vertical sides. When the top becomes the closest side, the particles again move vertically, but upward instead of downward.

8. Move the cylinder back up until the emitter is at its vertical center. Then, on the Modify panel, click the lower part of the Sides spinner to decrease the number of sides, one at a time.
   Each time you click, the particle streams traveling outward change, to move perpendicular to the vertical sides as they change position. You might also try rotating the cylinder, and note that the particle streams also rotate, like the spokes of a wheel.

9. In the Speed By Surface parameters, change Direction to Out Of Surface, and then move the cylinder up and down.
   The overall behavior doesn’t change much. Out Of Surface becomes more useful when you use the Control Speed Continuously option, as you’ll observe shortly.

10. In the Speed By Surface parameters, change Direction to Parallel To Surface, and then move the cylinder up and down.
    Now the particle behavior is effectively opposite of that with the other two options. When the particles are closer to the top or bottom, they move along the XY plane, and when they’re closer to the vertical sides, they move downward. If you want them to move upward instead, set Speed to a negative value.
    Next, you’ll discover how the Control Speed Continuously option alters particle behavior.

11. In the Speed By Surface parameters, choose Control Speed Continuously, and then drag the time slider.
    The particles spread out from the emitter, and then start orbiting the cylinder in a roughly cylindrical overall formation. The software continually checks to see which side of the cylinder a particle is closest to, and, if necessary, changes its direction to make it travel parallel to that side. You can affect the size of the particles’ orbits by changing their speed.
    Lastly, you’ll see how to contain particle motion within the cylinder.

12. Make the cylinder considerably larger:
    Radius=60 and Height=90. Activate the Perspective viewport, if necessary, and then press [F3] to set it to Wireframe view.

13. In Particle View, click the Speed 01 operator and set Direction to Random 3D.
14. Click the Speed By Surface operator. Set Speed to 300 if necessary. In the Direction group, choose Out Of Surface, and then drag the time slider.

After exiting the emitter, the particles always move away from the nearest surface, with the result that they end up milling about in the center of the cylinder.

15. Gradually increase the Speed value, up to 1,000 or so.

The particles start to spread out vertically, and eventually start moving so fast that they escape the cylinder. You can make them stay inside the cylinder by letting them accelerate more quickly, so they can turn before moving past the nearest surface.

16. Increase the Accel Limit setting until the particles no longer exit the cylinder.

17. Try giving the particles more room to move about in by increasing the size of the emitter. Also try changing other settings throughout the particle system to see their effects. The possibilities don’t end here, and the more you experiment, the more you’ll learn about how this powerful operator works.

### Interface

![Speed By Surface Operator Interface](image)
Chapter 11: Space Warps and Particle Systems

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

The first setting lets you choose whether the operator controls speed once or continuously.

**Set Speed Once**—The operator sets the speed for each particle once: when the particle enters the event.

**Control Speed Continuously**—The operator sets particle speed throughout the event. When you choose this option, the Continuous Speed Control group (page 2–172) becomes available.

**Speed**—The particle speed in system units per second. Default=300.

With the Control Speed Continuously option, you can turn off Speed. This causes Particle Flow to use the current particle speed.

Using a negative Speed value causes particles to move in the opposite direction of that effected by a positive speed.

**Variation**—The amount by which particle speed can vary, in system units per second. Default=0.0.

To obtain each particle’s speed, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Speed value. For example, if Speed=300 and Variation=100, then each particle’s speed would be between 200 and 400.

**Surface Geometry group**

Use these controls to assign objects to affect particle speed and direction. The list in this group shows the objects, or reference geometry, that the operator uses to control speed and direction.

If you don’t assign any objects, the current particle speed and direction are not affected.

You can assign multiple Surface Geometry objects, but if they’re not all emitters as well, the results can be difficult to interpret. In general, assign the same objects as Surface Geometry that your system uses as emitters.

**Tip:** For optimal performance, when moving particles with respect to high-polygon objects, create a low-poly proxy version to use as surface geometry, link it as a child of the high-poly object if necessary, and then hide the low-poly proxy.

Use the Add and Remove buttons to edit this list.

**Add**—Adds an object to the list. Click Add, and then click an object in the viewport.

**By List**—Adds multiple objects to the list. Click By List to open the Select Surface Objects dialog. This works just like the Select Objects dialog (page 1–78); highlight the objects to use to control speed and direction, and then click the Select button.

**Remove**—Removes an object from the list. Highlight the object in the list, and then click Remove.

**Animated Shape**—Turn on to allow particles to follow the surface of an object whose form is animated by morphing or with modifiers.

**Subframe Sampling**—When on, the operator acquires animation of the Surface Geometry shape on a tick basis (every 1/4,800th of a second) rather than a frame basis. This provides greater precision in allowing the particle positions to follow animation of the Surface Geometry object’s form.

**Speed by Material**—Varies particles’ existing speed and direction based on properties of the material applied to each Surface Geometry object. For example, if an object is assigned a black-and-white checkered diffuse map and you choose the Grayscale Multiplier option, particles near the white-checked areas move faster than those from the black-checked areas.

**Note:** For material-influenced speed to appear properly in the viewports, two conditions are required: at least one viewport must be set to a shaded display mode, and the material or map
must have Show Map In Viewport turned on in the Material Editor.

The options are as follows:

- **Grayscale Multiplier**—Lets material luminance control speed, with darker areas producing slower particles and lighter areas producing faster ones. The software multiplies the luminance of the material near each particle, converted to a percentage, by the particle’s current speed. A luminance of 0 converts to 0%, of 128 converts to 50%, and of 255 converts to 100%.

  For example, if the speed of a particle traveling at 50 units per second is influenced by a pixel whose luminance is 90, the resulting speed is 90/255*50, or about 17.6 units per second.

- **Signed Grayscale**—Works like Grayscale Multiplier, but the multiplier can be negative as well, causing reversal of motion. Signed Grayscale uses a material luminance value of 128 as the midpoint, and assigns it a multiplier of 0%. Luminance values from 0 to 127 result in multipliers of -100% to about -1%, respectively, and values of 129 to 255 result in multipliers of about 1% to 100%, respectively.

- **RGB as World XYZ Mult.**—Works like Grayscale Multiplier, but uses the intensity of the material’s red, green, and blue channels to affect particle speed on the world X, Y, and Z axes, respectively. So, for example, if the material pixel is pure red, that is, its RGB value is (255,0,0), then the particle will retain its current speed on the world X axis, but its speed on the Y and Z axes will be reduced to 0. Similarly, a medium-yellow pixel (128,128,0) will cause speed on the world X and Y axes to be reduced by half, and will cut speed on the Z axis to 0.

- **RGB as Local XYZ Mult.**—Works like RGB as World XYZ Mult., but uses the object’s local coordinates rather than world coordinates.

**Use Sub-Material**—When on, uses a sub-material from the Multi/Sub-Object material assigned to the Surface Geometry object to define speed.

This option allows usage of “invisible” materials for controlling particle speed. If the emitter uses a Multi/Sub-Object material but its geometry doesn’t use the ID that corresponds one of the sub-materials, the sub-material doesn’t appear. However, the operator can use it to calculate the density of particle placement. The software assumes the material to be applied to the entire object surface.

**Mtl ID**—Specifies the material ID of the sub-material to be used for particle speed control.

**Direction group**

The Direction drop-down list lets you specify which way the particles go after they’re born. Default=Surface Normals. In most cases, the actual direction also depends on the icon orientation. The primary exception is when Position > Location is set to Pivot.

Particle movement is always in a straight line unless influenced by other factors.

- **Surface Normals**—Each particle moves along a line perpendicular to the nearest face. The direction the surface faces doesn’t matter.

- **Out Of Surface**—Particles move away from the closest face.

**Tip:** You can use this option to confine particles to the interior of an object. Position the emitter inside the object, designate the object as the Surface Geometry, choose Control Speed Continuously, and choose Out Of Surface. Each time a particle comes close to a surface, it turns to travel directly away from the surface. Control the particles’ travel range with the Speed setting, but keep in mind that particles moving very fast might “escape” their container. If this happens, increase the Accel Limit setting; this lets the particles turn more quickly.
Parallel To Surface—Each particle travels parallel to the nearest face.

To make particles orbit an object, use this with Control Speed Continuously, and set appropriate Continuous Speed Control values (see the following section).

Divergence—When on, spreads out the particle stream. Use the numeric setting to define the extent of the divergence. Range=0 to 180. Default=0. The value can be animated.

This option is unavailable if Control Speed Continuously is chosen.

Tip: For a fountain-like spray, set Position > Location to Pivot, set Direction to Along Icon Arrow, set Divergence to the desired angle, and rotate the icon so its arrow points upward.

Continuous Speed Control group

When you choose the Control Speed Continuously option, these controls become available. Basically, these controls let the particles move about within the region of the Surface Geometry object rather than in a straight line away from the emitter.

Accel Limit—Sets the maximum acceleration. The higher this value, the more quickly particles can turn and change speed.

Tip: Use a lower Accel Limit value for smooth motion, and a higher value when greater accuracy is needed, such as when the particles should hit a small target. You can animate this setting (use Sync By > Event Duration) to specify different appropriate values, depending on the required results.

Unlimited Range—When on, the surface controls speed and direction of particles at any distance. When off, particles must be within a specified range. Default=on.

Range—The maximum distance, in system units, between the particles and controlling surface.

The Surface Geometry will not control particles beyond this distance.

Falloff Zone—The distance, in system units, beyond the Range value within which the Surface Geometry exerts partial control over particles. The degree of control diminishes from 100% at the Range distance to 0% at the Range+Falloff Zone distance.

Animation Offset Keying group

Choose the time frame for applying animated parameters. For an explanation, see Animation Offset Keying group (page 2–158).

Absolute Time—Any keys set for parameters are applied at the actual frames for which they’re set.

Particle Age—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.

Event Duration—Any keys set for parameters are applied to each particle starting when it first enters the event.

Uniqueness group

The Uniqueness setting enables randomization of speed variation, and randomization of direction with the Random 3D and Random Horizontal options.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

Keep Apart Operator

The Keep Apart operator, a member of the Speed operator family, lets you apply forces to particles

Particle View (page 2–125) > Click Keep Apart in an event or add a Keep Apart operator to the particle system and then select it.
Keep Apart Operator

to cause them to separate, in order to prevent or minimize collisions among particles. Alternatively, you can use a negative force to keep particles from separating too much. The operator works by controlling particle speed and acceleration.

Note: Keep Apart doesn’t use particle geometry; rather, it creates a spherical force field centered on the pivot of each particle. You can adjust the size of the force field by changing the particle size.

Tip: In certain cases, the default settings might not be sufficient to keep particles from interpenetrating. For increased separation, use higher values for Force and Accel Limit, choose Relative To Particle Size, and increase the Core % value.

**See also**

*Speed By Surface Operator (page 2–167)*

*Speed By Icon Operator (page 2–162)*

---

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Force**—The amount of force applied to the particles. Use positive values to separate particles,
or negative values to move them closer together. Default=100.0

**Acceleration Limit**—When on, lets you set a maximum acceleration value that can be applied to particles’ motion. When off, the software uses any necessary acceleration. Default=on, 1000.0.

Tip: Use a lower Accel Limit value for smooth motion, and a higher value when greater accuracy is needed, such as when the particles should hit a small target. You can animate this setting (use Sync By > Event Duration) to specify different appropriate values, depending on the required results.

**Speed Limit**—When on, lets you set a maximum speed value that can be applied to particles’ motion. When off, the software uses any necessary speed. Default=off, 600.0.

**Range group**

You can set a volume and falloff within which the force takes effect, either as absolute distances or relative to particle size. Default=Absolute Size.

**Absolute Size**—Choose this to set the core radius and falloff zone as absolute distances, in system units.

**Core Radius**—The distance from each particle’s pivot point, in system units, within which the force is applied at full strength. Default=10.0

**Falloff Zone**—The distance beyond the core radius, in system units, over which the force diminishes from full strength to 0. Default=10.0

**Relative to Particle Size**—Choose this to set the core radius and falloff zone as percentages, relative to the radius of each particle. The particle radius is determined by measuring the distance from the pivot point to the farthest corner of its bounding box.

**Core %**—The distance from each particle, as a percentage of the particle radius, within which the force is applied at full strength. Default=200.0

**Falloff %**—The distance beyond the core radius, as a percentage of the radius, over which the force diminishes from full strength to 0. Default=100.0

**Variation %**—The amount by which range values can vary randomly, as a percentage of the specified values. The software uses the same random variation value for both Core and Falloff values, whether absolute or relative. Default=0.0

For example, if you choose Absolute Size, set Core Radius to 40 and Falloff Zone to 20, and set Variation % to 50, then each particle’s actual core radius will be a random number in the range 20 to 60, and the falloff zone a random number in the range 10 to 30. For each particle, the software uses the same Variation % value, so if Core Radius is determined to be 20, then Falloff Zone would be 10.

**Scope group**

By default, the Keep Apart force keeps particles only in the current event (that is, the event that contains the Keep Apart operator) apart from each other when used locally, or particles in each event in the current flow (page 3–942) apart when used globally. These settings let you alternatively keep particles away from particles in other events or flows without affecting the behavior of latter. Default=Current Event.

**Current Event**—Keeps particles in the current event only away from each other.

When used globally, keeps particles in each event in the current flow apart from each other, but not apart from particles in other events in the flow.

**Current Particle System**—Keeps particles in the current event away from each other, and away from all other particles in the current flow (page
The particles not in the current event are not influenced by the Keep Apart operator.

When used globally, keeps apart and influences all particles in the current flow.

**Selected Events**—Keeps particles in the current event away from all particles in the events highlighted in the list below this choice. Particles not in the current event are not influenced by the Keep Apart operator.

When used globally, keeps all particles in the current flow apart from all particles in the events highlighted in the list below this choice, but influences only particles in the current flow.

After choosing this option, click items in the list to highlight them.

**Selected Particle Systems**—Keeps particles in the current event away from all particles in the flows (page 3–942) highlighted in the list below this choice. The particles not in the current event are not influenced by the Keep Apart operator.

When used globally, keeps all particles in the current flow apart from all particles in the flows highlighted in the list below this choice, but influences only particles in the current flow.

After choosing this option, click items in the list to highlight them.

**Uniqueness group**

The Uniqueness setting enables randomization of the Range (page 2–174) > Variation % calculations.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

**Script Wiring rollout**

This rollout appears in the parameters panel below the main operator rollout after you highlight the operator, right-click it, and then choose Use Script Wiring. Thereafter, a check mark appears next to the Use Script Wiring in the right-click menu, and the rollout appears whenever you highlight the operator. To turn off script wiring, choose Use Script Wiring again from the right-click menu.

Script wiring lets you use a script to control the Force and Range parameters, which you normally specify in the operator’s parameters. Place a Script operator (page 2–208) before the Keep Apart operator in the event, and then use it to define values in the particleFloat and particleVector channels. For an example of a script that sets particleFloat values, see particleFloat Sample Script (page 2–206).

On the Script Wiring rollout, choose either of the following:

**Use Script Float As**—Choose either of the following:
- **Not Used**—Particle Flow uses the Force setting specified in the Parameters rollout.
- **Influence**—Particle Flow applies the script particleFloat value to the Force value.

**Use Script Vector As**—Choose one of the following.
- Choosing Absolute Size Range or Relative Size Range makes the Range settings on the Parameters rollout unavailable.
  - **Not Used**—Particle Flow uses the Range (page 2–174) settings specified in the Parameters rollout.
  - **Absolute Size Range**—Particle Flow applies the script particleVector values to the Absolute Size Range values. The X component of the vector value is used for the core radius, and the Y component for the falloff radius.
  - **Relative Size Range**—Particle Flow applies the script particleVector values to the Relative Size Range values. The X component of the vector value is used for the core percent, and the Y component for the falloff percent.
Chapter 11: Space Warps and Particle Systems

Shape

Shape Operator

Shape is the default operator for defining the geometry used in the particle system. You can use it to specify particles in the shape of pyramids, cubes, spheres, or vertices, as well as particle size.

Note: All primitive particles created with Shape have pivot points in their geometric centers.

See also

Shape Instance Operator (page 2–178)
Shape Facing Operator (page 2–176)
Shape Mark Operator (page 2–183)

Interface

Shape Operator Interface

Shape—Sets the shape of the particles to Vertex or one of three geometric primitives. Default=Pyramid.

- Vertex—Use this option to create non-rendering particles whose sole attribute is their location. This can be useful when using script operators.
- Tetra—These tetrahedron-shaped particles have a four triangular sides. Having only four polygons, the tetra is the simplest of the rendering particle shapes.
- Cube—These box-shaped particles have six square sides, all the same size.

- Sphere—Creates spherical particles. The sphere has the most polygons of the rendering particle shapes, and its orientation isn’t obvious.

Size—Sets the overall size of the particles in system units. Default=10.0

Setting Size=0 makes the particles invisible.

Scale—Turn on to set the size of the particles as a percentage of the Size value. Use the numeric field to set the Scale percentage value. Default=100.

Scale is animatable, while Size is not. Also, turning on Scale creates the scale data that any Scale operators further on in the flow can work with.

Shape Facing Operator

The Shape Facing operator creates each particle as a rectangle that always faces a particular object, camera, or direction. For effects like smoke, fire, water, bubbles, or snowflakes, use Shape Facing with a material containing appropriate opacity and diffuse maps.

By default, the particles’ top and bottom sides are parallel to the horizontal plane. The Orientation setting lets you change this default alignment.

Note: For the Shape Facing operator to be able to calculate the particle orientation, it must know the current particle position. For this reason, always place the Shape Facing operator below a Position operator in an event.

Shape Mark Operator (page 2–183)
Interface

Look At Camera/Object group

Use this control for defining the camera or object toward which the particle will face. This object is known as the Look At object. For the technically minded, the facing is maintained by keeping each particle’s local Z axis pointed at the Look At object, or when Use Parallel Direction is on, aligned with the vector between the Particle Source icon and the Look At object.

Name—After picking a Look At object, its name appears here.

Pick Camera or Object—Click this button, and then select a camera or object in the scene to use as the Look At object. The mouse cursor changes to a cross shape when positioned over a valid object.

Use Parallel Direction—When off, all particles continuously rotate to stay facing toward the Look At object. Each particle’s orientation varies because its location differs from those of the others. When on, all particles face in the same direction, defined by an imaginary line between the Particle Source gizmo center and the Look At object. Default=off.

Size/Width group

Use these settings to specify the coordinate system for setting the size, as well as the size parameters. The numeric settings in this group are not animatable.

In World Space—Sets the absolute size in system units, using the World coordinate system.

Units—with the In World Space option, sets the particle size in system units. Range=0 to 1000000000. Default=1.

In Local Space—Sets particle size relative to the existing size, in local space. The software uses the dimensions of the existing shape to determine the size of the “facing rectangle.”

Inherited %—Sets the facing particles’ size as a percentage of the existing size. Range=0 to 100. Default=100.

In Screen Space—Sets the facing particles’ size as a percentage of the screen width. The actual size of each particle changes as necessary throughout the animation, depending its distance from the camera, to maintain a constant size from the camera’s point of view.

This option is available only when the Look At object is a camera, and Use Parallel Direction is off.

Proportion %—Sets the particle size as a percentage of the screen width. Default=1.
**Variation %**—Sets the percentage by which particle size can vary. Default=0.

**Pivot At**—Specifies the part of the particle around which rotation is performed when maintaining the facing direction. The choices, available from the drop-down list, are Top, Center, and Bottom. Default=Center.

With Top and Bottom, the center of the corresponding side is used as the particle center for rotation.

This option is useful, for example, when particles are lying on a surface, and each particle is an explosion. In this situation, you’d probably want the entire particle rectangle to appear above the surface, so you’d set Pivot At to Bottom.

**W/H Ratio**—Defines the aspect (width-to-height) ratio of the shape rectangle.

Adjust this ratio to that of the particle-map imagery. For the commonly used TV aspect ratio of 4:3, set W/H Ratio=1.33. The parameter is not animatable. Range=0.001 to 1000. Default=1 (square particles).

This value is not animatable.

**Orientation**

Use this drop-down list to choose how particles rotate on the axes not specified by the Look At direction. Default=Align to Horizon.

**Align to Horizon**—Keeps the top edge aligned with the horizon (the world XY plane).

**Align to Speed Follow**—Uses the right side of each particle as the leading edge, so the top and bottom edges are aligned with the direction of particle motion.

**Random**—Orients the top edge at random.

**Allow Spinning**—To spin the particles, choose this option, and in the same event use a Spin operator (page 2–154). In the latter, set Rotation Axis to Particle Space and use the default axis values: X=0, Y=0 , Z=1.

**Uniqueness group**

The Uniqueness setting enables changing the randomization of the size/width variation.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Shape Instance Operator**

- **Particle View (page 2–715)** > Click Shape Instance in an event or add a Shape Instance operator to the particle system and then select it.

Shape Instance lets you use any reference object (page 3–1002) in the scene as particles. You can effectively define only one reference object per event, but the object can comprise any number of sub-objects, each of which Particle Flow can treat as a separate particle. Also, using tests, you can divide the particle stream into multiple branches and define a different particle shape for each.

As the name of the operator indicates, reference geometry is instanced into the particle system. Thus, any physical changes you make to the original geometry are reflected instantly in the particle system. If you hide the original geometry, the particles still appear. However, if you delete the original geometry, the particles are deleted as well.

**Using Transform-Animated Reference Objects**

You can create animated particle shapes by animating the reference object with modifiers, and then turning on Animated Shape. However, Shape Instance ignores any rotational and positional transformations applied directly to the reference object; it uses only the pure scale component. For
example, if you scale an object non-uniformly using the View reference coordinate system, the result might skew the object’s shape. Because the skewing is the by-product of a rotational transform, it wouldn’t be reflected in the particles’ shape. However, modifiers and comparable functions that contain transformations applied to the reference object are reflected in the instanced particles. For example, if you want particles to use rotational transforms applied to the reference object, use the Reset XForm function on the reference object. Reset XForm is available from the Utilities panel.

Tip: Particle Flow can, however, use rotational and positional animation applied to descendant objects in a hierarchy, when you use the entire hierarchy as a single particle. To do this, create a hierarchy, animate the descendant objects, and then designate the parent as the reference object. Do not turn on Separate Particles For > Object And Children. You’ll find a procedure illustrating this, below.

When using an animated reference object, it is recommended that you hide the reference object after instancing it in the particle system.

**Procedure**

**Example: To use the reference object’s rotational and positional animation in the particle system:**

1. Create an object you want to use as the particle shape, such as a teapot, and a Dummy helper object.

2. Animate the teapot using the Move and Rotate tools.

3. Use the Align tool to center the teapot to the dummy.

   This step isn’t necessary, but it can help to obtain more consistent results.

4. Link the teapot as a child of the dummy (drag from the teapot to the dummy).

   You can use any object as the parent, but using a dummy, which doesn’t render, lets you animate all instanced particles visible in the final animation.

5. Create a default Particle Flow system.

6. In Particle View, delete the Rotation operator.

7. Replace the Shape operator with a Shape Instance operator.

8. In the Shape operator parameters, designate the dummy as the Particle Geometry Object.

9. Turn on Animated Shape.

10. For sequential animation, which can be more interesting visually, in Animation Offset Keying, set Sync By to Particle Age or Event Duration.

**Particle Geometry group**

Use this control for defining the object to be used as the particle geometry. This object is known as the **reference object**.

**[button]**—Click this button, and then select a geometry object in the scene to be used as the particle shape. The mouse cursor changes to a cross shape when positioned over an object that’s valid for use as a reference object. Valid objects include *multi-shape* objects such as groups and hierarchies; see **Separate Particles For group** (page 2–181).

After picking a reference object, its name appears on the button.

You can use almost any geometry object as a reference object. By default, the operator automatically converts closed splines to rendering geometry by “filling in” the area defined by the shape outline. To use the shape outline instead, select the original shape and, on the Modify panel > Rendering rollout, turn on Display Render Mesh. You needn’t turn on Renderable, but changes to all other Rendering rollout settings, such as Thickness and Sides, are reflected in the rendered particles.

Particle Flow does not automatically “fill in” open shapes such as Line (non-closed) and Arc. To render these shapes when using them as particles, turn on Modify panel > Rendering rollout > Display Render Mesh.

If a Shape Instance operator is in effect for which the geometry object is not defined, and the viewport display type is set to Geometry, then the particles appear in the viewports as X characters.

**Note:** If a multi-shape object used as a reference object comprises objects both with and without materials applied, and Acquire Material is on, Particle Flow will apply the first available material to any objects without materials applied.

**Note:** You can use a NURBS surface as a reference object, but not a NURBS curve. To use a NURBS curve as particle geometry, first convert it to a surface using a method such as the Cap function.

**Tip:** For best results, when using an animated reference object, it’s highly recommended that you hide the original object before rendering, or use Object Properties to turn off its Renderable check box.

**Note:** If using a group as a reference object, make sure the group is closed before selecting it.
Selecting an open group will add only the group member you click, not the entire group.

**Separate Particles For group**

3ds Max provides a number of methods for combining disparate objects into single entities, including grouping, building hierarchies with linking, and attaching. By default, when using such a *multi-shape* object as particle geometry, each particle comprises all member objects. Alternatively, you can instruct Particle Flow to treat each member object as a separate particle with these options. When on, the software uses each member object as a single particle, in left-to-right order according to its X-axis position, by default. So, for example, if you create text in the Front viewport, assign it as reference geometry, and turn on Object Elements, the letters come out in the proper order.

You can vary the order randomly by turning on *Multi-Shape Random Order*.

You can turn on any combination of Separate Particles items. All are off by default.

**Group Members**—When on, group members are treated as separate particles.

**Object and Children**—When on, linked objects are treated as separate particles.

**Object Elements**—When on, element sub-objects of a single mesh object are treated as separate particles.

**Vertices/Faces**—Show the number of vertices and triangles per particle. If the reference geometry is multi-shape and the appropriate check boxes in the Separate Particles are on, then these displays show an average vertex/face count.

**Number of Shapes**—Shows number of different particle shapes. This number is always 1 unless the reference geometry is multi-shape and the appropriate check boxes in the Separate Particles

For group are on, in which case this displays the number of resulting different shapes.

**Scale (%)**—Specifies a uniform scaling factor for all particles. Range=0 to 100000. Default=on, 100.

The center of scaling for multi-shape object members treated individually depends on how the objects are combined. For grouped and linked objects, the scaling is done about the objects’ pivot points. For object elements, the scaling center is the geometric center of each object; that is, the averaged location of all the vertices.

This value cannot be animated. To animate particle size, use the *Scale operator* (page 1–441).

**Variation (%)**—Specifies a randomized percentage of scaling variation. Use the Uniqueness setting to change the randomization. Range=0 to 100. Default=0.

This value cannot be animated. To animate scaling variation, use the *Scale operator* (page 2–156) operator.

**Acquire Mapping**—When on, all mapping data from the reference object is transferred to particles. Default=on.

**Acquire Material**—When on, material data from the reference object is transferred to particles. Default=on.

If the reference object is a group, with different materials applied to the group members, the software creates a new Multi/Sub-Object material containing all of the materials and uses it as the particle material.

Tip: Because materials are “sticky” in Particle Flow, if you turn off Acquire Material after specifying a reference object with an attached material, the material remains applied to the particles. To avoid applying the instanced shape’s material to the particles, turn off Acquire Material before specifying the reference object.
Multi-Shape Random Order—When on, assigns shapes to particles in random order. When off, Particle Flow emits each shape in the multi-shape object as a single particle, in the order of the shape’s X coordinate. In other words, the shape with the lowest X-axis coordinate is emitted first, then the one with the next highest, and so on. The option is available only if at least one of Separate Particles For group check boxes is on. Default=off.

For example, if you want the particles to spell out a word or phrase, use extruded text created in the Front viewport as the reference object, turn on Separate Particles For > Group Elements, but leave Multi-Shape Random Order off.

Animated Shape—When on, particles use any animation in the reference object, including cyclic animation applied with the Parameter Curve Out-of-Range Types controls. When off, the particles are not animated.

With this option, you can use the Animation Offset Keying controls to specify how to synchronize the reference-object animation with the particles. See the next section.

Note: A particle that uses this option is animated only while in the event containing the Shape Instance operator. If it moves to another event that doesn’t contain a shape operator, it keeps the same shape, but the animation stops. The easiest way to keep the animation going from event to event is to place the Shape Instance operator in the global event (page 3–949). Otherwise, you need to place the operator in each event in which the particle should be animated.

Acquire Current Shape—When on, Particle Flow acquires the particle shape from the reference object as each particle enters the event. Thus, if the reference object is animated, particles that enter at different times get different shapes. However, these shapes are not animated. When the option is off, the shape is acquired from frame 0. Default=off.

This option is available only when Animated Shape is off.

Animation Offset Keying group

These controls are available only when Animated Shape is on.

Sync By—Lets you choose how to synchronize reference-object animation with the particles.

• Absolute Time—All particles have the same shape at any given moment.
• Particle Age—Animation of the reference object is synchronized with particle age: Frame 0 of the reference-object animation corresponds to the frame of each particle’s birth.
• Event Duration—Frame 0 of the reference-object animation corresponds to the moment the particle enters the event.

Rand Offset—When on, randomly varies the start of each particle’s animation. Use the numeric setting to specify the number of frames by which the animation start can vary.

Update Particle Shape—Refreshes instanced particle shapes from the reference object. Use this after changing an object in a hierarchical reference object.

In most cases, Particle Flow automatically updates instanced particles when changes are made to the reference object. However, in some cases, when you change an object deep in a hierarchy, the particle instances might not be updated. In such a case, click Update Particle Shape to refresh the instances.

Uniqueness group

The Uniqueness setting enables changing the randomization of the scale variation, animation offset, and the multi-shape random order.

Seed—Specifies a randomization value.
New—Calculates a new seed using a randomization formula.

**Shape Mark Operator**

*Particle View (page 2–125) > Click Shape Mark in an event or add a Shape Mark operator to the particle system and then select it.*

Use the Shape Mark operator to replace each particle with either a rectangle or a box cut out from the particle geometry with an image mapped onto it. The image can be animated and the animation can be synchronized with particle events.

A typical application of Shape Mark would be to leave marks after particles impact objects in the scene. For example, when a torpedo hits a boat and explodes, you could use Shape Mark to leave scorch marks on the boat surface.

Tip: By default, the mark left by Shape Mark is always rectangular, no matter what shape the particles are. To leave a differently shaped mark, choose the Shape group > Rectangle option, and use a material (page 2–186) in the same event with transparent areas to define the mark’s outline. For example, apply a Mask map to the material’s Opacity channel, and to the map’s Mask channel, apply a bitmap containing an alpha channel. On the Bitmap Parameters rollout, set Mono Channel Output to Alpha.

Note: With its default settings, the Shape Mark operator can generate coplanar faces, which the mental ray renderer cannot render well. If you want to use mental ray rendering with Shape Mark, adjust the operator’s settings as follows:

- In the Shape group, choose Box Intersection.
- Set Surface Offset to 0.01.
- Set Offset Variation to 0.005.
- Set Vertex Jitter to 0.002.

With these settings, faces are no longer coplanar, and the mental ray renderer gives better results.

**See also**

*Shape Operator (page 2–176)*
*Shape Instance Operator (page 2–178)*
*Shape Facing Operator (page 2–176)*

**Procedure**

**Example: To use Shape Mark:**

1. Determine which object is to receive the marks; this will be the **contact object**. Apply a deflector to this object.
2. Set up your particle system with an event that causes particles to collide with the contact object deflector.
3. At the end of this event, add a **Collision test** (page 2–212).
4. In the Collision test, designate the deflector from step 1.
5. Create a new event with the Shape Mark operator, and wire the Collision test to this event.
6. In the Shape Mark operator > Contact Object group, designate the object from step 1. Change the other Shape Mark settings as necessary.

Now, when the particles strike the contact object, they disappear, leaving marks on the object.

If you want the particles to bounce after leaving marks, rather than disappearing, use a **Collision Spawn test** (page 2–215) instead, and turn off its Delete Parent check box. The spawned particles become the marks, and the original particles remain in the first event.

7. Optionally, add a Material operator to define the surface characteristics of the marks.
Chapter 11: Space Warps and Particle Systems

Interface

### Contact Object group

Use this control for defining the object on which marks are to be left.

**[button]**—Click this button, and then select an object in the scene to use as the contact object. The mouse cursor changes to a cross shape when positioned over a valid object.

After picking a contact object, its name appears on the button.

**Align to Surface Animation**—When on, Shape Mark takes into account surface changes due to vertex animation of the contact object. If *Shape* (page 2–185) is set to Rectangle, then the mark changes its orientation and position to appear be stuck to the surface of the contact object. If Shape is set to Box Intersection, then the mark changes shape along with that of the contact object. When off, only transformation of the contact object is taken into consideration. Default=off.

Turn this on only if there is significant vertex animation at the contact point, such as with an animated water surface.

**Warning:** This option requires significant CPU and memory resources.

### Orientation group

**Align To**—Depending on the setting for *Shape* (page 2–185), Shape Mark creates either a rectangle or a box cutout on the contact geometry. The Orientation setting specifies how the shape is oriented. In the mark’s local coordinate system, the X axis is Length, the Y axis is Width, and with the box cutout, Z is height. The Z axis is perpendicular to the surface of the object at the contact point.

The alignment choices are as follows:

- **Speed**—The Length direction is parallel to the projection of the particles’ speed vector onto the contact plane.
Particle X/Y/Z—The Length direction is parallel to the projection of the particle’s local coordinate axis X, Y, or Z, respectively, as the particle moves toward the contact object.

Random—Uses a random Length direction in the contact plane.

Divergence—Applies a range of random variation, in degrees, to the orientation of the Length direction. Unavailable when using the Random option.

Size group

Use these settings to specify the coordinate system for setting the size of the mark, as well as the size parameters. The numeric settings in this group are not animatable.

In World Space—Sets the absolute size of the mark in system units, using the World coordinate system.

Width/Length—With the In World Space option, sets the particle dimensions in system units. Range=0 to 1000000000. Default=1.0.

In Local Space—Sets the mark size relative to the existing particle size, in local space. The software uses the dimensions of the existing shape to determine the size of the “facing rectangle.”

Inherited %—Sets the percentage of the mark size, relative to the existing particle size. Range=0 to 100. Default=100.0.

Variation %—Sets the percentage by which particle size can vary. Default=0.0.

Impact Angle Distortion—When on, increases the Length value of the mark according to the particle’s angle of approach. This effectively stretches the mark shape if particle approaches the contact geometry at a low angle. Available only when Align To is set to Speed. Default=off.

For example, if a drop of paint hits a surface perpendicularly, it creates a circular mark, but if it hits the surface at a lower angle, the resulting shape is an ellipse.

Distor(tion) Max %—Sets the maximum percentage by which the software may stretch the mark. Available only when Impact Angle Distortion is on. Default=1000.

With very low angles of approach, the stretching factor can become very high. For example, value 500% means that the stretching factor cannot exceed 5.

Shape group

These settings let you specify the mark-making object as a rectangle or a box. Default=Rectangle.

Rectangle—The mark shape is a two-faced rectangle.

When using a material with Shape Mark, always choose this option.

Box Intersection—With this option, the software creates a box for each particle that leaves a mark, and derives the mark shape from a Boolean intersection between the contact object and the box.

Box Height—Sets the height of the box used with the Box Intersection method. Available only with Box Intersection. Default=10.0.

Allow Multiple Elements—When on, particles can leave marks on all parts of contact objects that contain multiple elements. When off, a particle marks only the first element it collides with. Available only with Box Intersection. Default=off.
Chapter 11: Space Warps and Particle Systems

Chapter 11: Space Warps and Particle Systems

Particles falling onto a two-element cylinder
Left: Allow Multiple Elements is off; Right: Allow Multiple Elements is on.

Continuous Update—When on, the shape of the mark is recalculated at each frame, according to the current positions of the particle and the contact surface. This option can consume a great deal of CPU time. Available only with Box Intersection.

Generate Mapping Coords.—Allows correct application of the shape mark when using a mapped material. Default=on.

If you’re not using a mapped material, you can save memory by turning this off.

Pivot Offset %—Shifts the position of the shape mark along its length dimension with respect to the pivot of the impacting particle. Default=0.0. Range=-50.0 to 50.0.

By default, the center of the mark’s length dimension coincides with the point where the particle’s pivot strikes the contact object. This setting lets you offset the mark’s position to anywhere along its length.

Note: The width dimension and the Box Intersection’s height dimension are always centered at the intersection of the particle pivot and the contact object’s surface.

Surface Offset—Specifies the distance of the shape mark above the contact object’s surface. Default=0.001.

The mark is slightly elevated above the contact geometry to achieve the visual effect of the mark spot overlapping the contact geometry. This parameter is not animatable.

Offset Variation—Specifies the maximum extent of a random variation in the actual surface offset among particles. Default=0.0.

Adjusting this value can help to alleviate rendering artifacts with overlapping marks.

Vertex Jitter—Specifies the maximum extent of a random variation in the positions of vertices of marks created using the Box Intersection method. Available only with the Box Intersection method. Default=0.0.

Adjusting this value can help to alleviate rendering artifacts with overlapping marks.

Uniqueness group
The Uniqueness setting enables changing the randomization of the size/width variation.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

---

Material and Mapping

Particle Flow provides three operators for applying materials to particles. To give the same appearance to all particles throughout an event, use Material Static Operator (page 2–187). If you’re using a compound material such as Multi/Sub-Object (page 2–1594), you can assign different sub-materials to different particles with the Material Frequency operator (page 2–189). And to assign materials that change in appearance over time, use the Material Dynamic operator (page 2–191).

Related to this is the Mapping operator (page 2–195), which lets you give the same mapping coordinates to the entire surface of each particle in an event, thus using a single pixel from a material
to color the particles. By animating the mapping coordinates, you can cause the particles to change color over time. This is particularly effective with a gradient material.

The Bitmap map (page 2–1631), used in conjunction with Material Dynamic, lets you assign different frames from an image sequence to particles based on the particle age, among other effects.

Following are some items to keep in mind when using materials with Particle Flow:

- A material is a static property of an event. It does not travel along with the particles from one event to the next. A particle's material ID does, but its material does not. If you want particles always to use the same material, define the material in the global event (page 3–949) with a Material operator or a Shape Instance operator (page 2–178). Otherwise, you need to define it in each local event.

- The primitive particle shapes available with the Shape operator (page 2–176) do not have mapping coordinates. The Mapping operator (page 2–195) applies the same mapping coordinates to each particle's entire surface, so it's not suitable in this situation. If you want to apply image-based materials to particles, use Shape Instance (page 2–178) instead.

- If you use a Material operator with Shape Instance (page 2–178), be sure to apply mapping coordinates to the reference object(s) (page 3–1002). You can do this by making sure the object’s Generate Mapping Coords option is on (if available), or applying a UVW Map modifier (page 1–922) or Unwrap UVW modifier (page 1–878). If you don’t apply mapping coordinates, the system generates a Missing Map Coordinates warning when you render the scene.

- If you use an object with a material already applied as a reference object (page 3–1002) for instanced particles, you don’t need a Material operator in the same event. However, the material appears only in the event containing the Shape Instance operator (page 2–178); it does not persist from event to event.

- If you use the Cache operator (page 2–197) with Update set to Always, toggling the Material Editor > Show Map In Viewport switch causes Particle Flow to recalculate the cache.

- You can drag a material from the Material Editor to a Particle Flow source icon, but the material will not have any effect on the system. You must use a Material operator or Shape Instance to apply materials to particles in Particle Flow.

- Once you’ve assigned a material to a Material operator, the material shows up in the Material Editor as “hot”; that is, triangles appear in the corners of its sample slot. However, because of the nature of the Particle Flow data structure, the Material Editor functions Select By Material and Get Material > Browse From Selected do not work correctly with Particle Flow systems. You can, however, use Get Material > Browse From Scene.

---

### Material Static Operator

Particle View (page 2–125) > Click Material Static in an event or add a Material Static operator to the particle system and then select it.

The Material Static operator lets you give particles material IDs that remain constant throughout the event. It also lets you assign a material to each particle based on its material ID. The operator can assign the same material ID to all particles, or different IDs to successive particles on a cyclical or random basis. The most common usage of this latter capability is with a Multi/Sub-Object material, for applying a different material to each particle.
See also

Materials and Mapping in Particle View (page 2–186)
Material Frequency Operator (page 2–189)
Material Dynamic Operator (page 2–191)

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

Assign Material—When on, the operator assigns a material to the particles. Default=on.

[button]—Use this button to assign a material to the operator. Click the button and then use the Material/Map Browser to choose the material. Alternatively, drag the material from a Material Editor sample slot to the button. After you assign a material to the operator, its name appears on the button.

Assign Material ID—When on, the operator defines a material ID number for each particle. Default=off.

Show In Viewport—When on, the material is shown applied to the particles in the viewports.

Assignment Method

The Material Static operator gives you a choice of three different methods for assigning Material IDs to particles:

Material ID—Assigns the same material ID to all particles. Use the numeric field to set the ID value.

Cycle—Assigns each particle a material ID in the range 1 to N, where N=# Sub-Materials, in increasing sequential order. The first ID assigned is 1, then 2, then ..., then N, then 1 again, and so on.

Random—Assigns each particle a random material ID in the range 1 to N, where N=# Sub-Materials.

# Sub-Materials—The highest ID number assigned to particles using the Cycle or Random option.

In general, set this to the same number of sub-materials in the Multi/Sub-Object material. If you set it to a smaller number, the operator will use only that many sub-materials, starting with the first and counting upward.

Note: The software automatically sets this value to the number of sub-materials in the material, once only, the first time you apply the material to the operator. Any subsequent changes in the material itself, or applying a different material to the operator, will not change or update the setting.

Rate group

These settings let you choose the basis on which the operator changes material ID assignments, and specify the rate of change.

Per Second—Sets the number of times per second that the assigned material ID is incremented.
If this value is the same as the rate at which particles enter the event, then one ID is assigned per particle. If it’s lower, then multiple particles are given the same ID, or if it’s higher, then the software increments the assigned ID faster than 1 per particle.

For instance, if particles enter the event at intervals of 1/60 of a second, and Per Second=30, then each pair of particles will be assigned the same ID. Or if particles enter the event at intervals of 1/15 of a second, and Per Second=30, then the ID is incremented (or changed randomly) twice per particle.

**Per Particle**—Sets the number of particles that must appear before material ID assignment changes. For example, if you set Per Particle=3, the material ID changes every three particles.

If you set Per Particle to a number less than 1.0, the software then moves through the sub-material list more rapidly than one (or more) particle per ID. That is, the software divides this value into 1.0, and adds the result to the current material ID to obtain the next one. For example, with eight sub-materials, if you set Per Particle=0.33, and use the Cycle option, the following series of IDs will result: 1, 4, 7, 2, 5, 8, 3, 6, 1, ... In general, this option is useful only with the Cycle option.

**Loop**—When on, and the last ID has been assigned, the software loops back around to the first ID and continues the cycle. When off, the software assigns the last cycle ID to all subsequent particles. Available only with the Cycle assignment method. Default=on.

For example, say you want the first eight particles that enter the event to use different materials, and all subsequent particles to use a ninth material. To do so, you would create a nine-sub-material Multi/Sub-Object material and assign it to the Material Static operator. Turn on Assign Material ID, choose the Cycle assignment method, and set # Sub-Materials=9. For Rate, use the default settings of Per Particle and 1.0. Lastly, turn off Loop.

**Uniqueness group**

The Uniqueness setting varies the sequence of assigned IDs with the Random option.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

The Material Frequency operator lets you assign a material to an event, and specify the relative frequency with which each sub-material appears on the particles. Typically, the material is a Multi/Sub-Object or other compound material, and you specify the frequency by setting a percentage for each of up to 10 different sub-materials (or material ID). The software assigns IDs to particles in a random sequence, based on these percentages. You can also use other materials that use sub-materials, such as Double Sided and Top/Bottom.

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Assign Material**—When on, the operator assigns a material to the particles. Default=on.

**[button]**—Use this button to assign a material to the operator. Click the button and then use the Material/Map Browser to choose the material. Alternatively, drag the material from a Material Editor sample slot to the button. After you assign a material to the operator, its name appears on the button.

**Assign Material ID**—When on, the operator defines a material ID number for each particle, and enables the remaining parameters. Default=on.

In general, this should remain on. Particle Flow uses the material ID with compound materials to know which sub-material to assign to a particle.

**Show In Viewport**—When on, the material is shown applied to the particles in the viewports.

**# Sub-Materials**—Displays the number of sub-materials in the assigned material.

**Material ID #1–10**—Specifies the relative likelihood of particles to be assigned the corresponding material ID. Assign values for all IDs, or sub-materials, in the material that you want to have applied to the particles. So, for example, with a Multi/Sub-Object material containing five sub-materials, you’d set values for Material IDs #1-5.

This value is not absolute, but relative to the other settings. To follow the previous example, if you wanted all five materials to appear with equal frequency, you’d set the same non-zero value for Material IDs #1-5; the actual value wouldn’t matter. On the other hand, if you wanted the materials to appear with decreasing frequency, you’d set the lower Material ID settings to relatively higher values; say 100, 80, 50, 33, and 10. In this case, each particle would twice as likely to be assigned material ID 1 as it would material ID 3, and one-tenth as likely to be assigned ID 5 as it would ID 1.

The actual sequence of material ID assignments is random, and can be varied by changing the Uniqueness Seed setting.

**Uniqueness group**

The Uniqueness setting varies the random sequence of assigned IDs.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.
Material Dynamic Operator

The Material Dynamic operator lets you give particles material IDs that can vary during the event. It also lets you assign a different material to each particle based on its material ID. When used with an animated texture (page 3–908), this lets you assign a different frame or map to each particle based on its total age or the amount of time it has spent in the current event. In this context, one example of an animated texture is a material that uses a multi-frame bitmap, such as an AVI file, as the Diffuse Bitmap map (page 2–1631). Other examples of animated textures are materials that use the Particle Age map (page 2–1675) or the Particle MBlur map (page 2–1676). Alternatively, you can use different sub-materials from a compound material such as Multi/Sub-Object.

Note: When using Object Motion Blur, if an event contains a Material Dynamic operator that uses a material with a Particle Age/MBlur/Bitmap map, the event should not also contain a Delete operator, or a Spawn or Collision Spawn test. Also, the event should not contain any tests that are wired to another event. The only exception to this is the Age Test operator when set to Absolute Time without any variation; that is, all particles leave the event at the same time. This applies to the use of Object Motion Blur only; there are no restrictions with Image Motion Blur.

Procedure
Example: To assign animation frames to particles based on age:

1. Prepare a file to be used as the animated bitmap. This can be a multiple-frame format such as AVI, or an image file list (IFL file) that points to a sequence of still images. With the latter, you can use images in a format such as Targa that contain predefined alpha channels to specify particle opacity selectively.

2. Open the Material Editor, and assign a Bitmap map as the Diffuse map.

3. Use the Select Bitmap Image File dialog to assign the file from step 1 as the bitmap. This dialog appears automatically when you first assign a Bitmap map; alternatively, click the Bitmap button on the map’s Bitmap Parameters rollout.

4. On the map’s Time rollout, turn on Sync Frames To Particle Age.

5. If you want to use the image background or alpha channel to define transparency, on the Maps rollout, copy this map to the Opacity slot, and set the parameters accordingly.

6. At the material level, turn on Show Map In Viewport.

7. Add a camera to the scene and set it up as desired. Activate the Perspective viewport and press the C key to set the viewport to show the camera view.

8. Create a default Particle Flow system.

9. Open Particle View.

10. Replace the Shape operator with a Shape Facing operator.

Using this operator makes it easier to see the animation.

See also

Materials and Mapping in Particle View (page 2–186)

Material Static Operator (page 2–187)

Material Frequency Operator (page 2–189)
Chapter 11: Space Warps and Particle Systems

11. Click the Shape Facing operator, and in its rollout, click the Look At Camera/Object button, and then select the camera.

12. In the Size/Width group, increase In World Space > Units to about 15.

13. Add a Material Dynamic operator to Event 01, and assign it the material from the beginning of this procedure.

14. Turn on Show In Viewport.

15. In the Animated Texture group, make sure Same As Particle ID is chosen, and turn on Reset Particle Age.

Turning on Reset Particle Age causes the software to set particles to age 0 as they enter the event. In this example, the particles are born in the event, so technically it's not necessary to turn on Reset Particle Age. However, it's a good habit to get into to ensure that the animation always plays from the first frame.

16. Play the animation.

In the viewport, the bitmap animation advances as the particles move, but all the particles show the same frame, regardless of age. This is anomalous behavior related to the limitations of viewport interactivity. The particles render correctly, however.

17. Render the animation.

As each particle is born, it begins displaying the animation from the first frame. At each frame, each particle’s age is incremented, and it displays the next frame from the applied map.

**Example: To use the Particle Age map:**

The Particle Age map (page 2–1675) applies up to three different colors or maps to particles throughout their life span, gradually changing from one to the next as the particles age. This effect can be used, for example for sparks flying from a fire: At first they’re yellow; then, as they cool down, they turn red, and finally they become gray ashes. In order for Particle Age to know how far a particle has progressed through its life span, the particle has to be given a finite life. You do this using the Delete operator (page 2–146).

1. Start or reset the program, and add a Particle Flow system.

2. Open Particle View and the Material Editor. Position them side by side.

3. In Particle View, add a Material Dynamic operator and a Delete operator to Event 01. For Particle Age to work, the Delete operator must be in the same event as the Material Dynamic operator. Alternatively, you can add the Delete operator to the global event (page 3–949) so that it affects every event.

4. Click the Delete operator, and in the parameters panel, choose By Particle Age, and set Life Span=100 and Variation=0. This gives each particle a life span of 3 1/3 seconds.

5. Click the Material Dynamic operator.

6. In the Material Editor, assign a Particle Age map as the Diffuse map. On the Particle Age Parameters rollout, set three different colors, such as red, green, and blue. Also change the Age percentage values as necessary. For example, if you want each particle to show the second color a third of the way through its life instead of halfway, change Age #2 to 33.

7. Drag the active material from its sample slot to the material button on the Material Dynamic parameters rollout in Particle View. When the Instance (Copy) dialog appears, click OK to accept the default choice: Instance.

8. In the Material Dynamic parameters, make sure Assign Material ID is on.
If it isn't, the particles all change color at the same time.

There's no need to turn on Show In Viewport; the Particle Age map doesn't appear in the viewports.

9. Render the animation, or a few representative frames.

As each particle falls, it gradually changes color, with the oldest particles changing first.

Tip: You needn’t actually delete the particles to use this method. There are several ways to avoid this. You could set Life Span to a higher number than the length of the animation, and then, in the Particle Age map parameters, lower the Age #2 and Age #3 settings. Or, if you’re using a local Delete operator, you could use an Age test (page 2–211) to move the particles into another event just before they’re scheduled to be deleted. In that case, to avoid an abrupt color change, you might want to add to subsequent events a Material Static operator (page 2–187) with a material that uses the same final color or map as the Particle Age map.

### Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Assign Material**—When on, the operator assigns the specified material (see next parameter) to the particles. Default=on.

**[button]**—Use this button to assign a material to the operator. Click the button and then use the Material/Map Browser to choose the material. Alternatively, drag the material from a Material Editor sample slot to the button.

After you assign a material to the operator, its name appears on the button.
Assign Material ID—When on, the operator defines a material ID number for each particle. Default=on.

In general, this should remain on. Particle Flow uses the material ID with the Particle Age map to find the particle’s other properties, including its life span and current age. And it uses the material ID with compound materials to know which sub-material to assign to a particle.

Show In Viewport—When on, the material is shown applied to the particles in the viewports when the particles are displayed as geometry.

Assignment Method
The Material Dynamic operator lets you assign Material IDs to particles in several different ways, depending on whether you’re using an animated texture or a compound material. Default=Same As Particle ID.

Animated Texture group
Same As Particle ID—Assigns the same material ID to a particle as its particle ID. Choose this when using a material containing an animated texture, such as a Bitmap, Particle Age, or Particle MBlur map.

Note: Particle Flow assigns Particle IDs consecutively to particles at birth, starting with 0. Although the highest possible Particle ID is over 2,000,000,000, the highest possible material ID is 65535. Thereafter, the numbering sequence starts again at 0. Thus, when using a Particle Age map in a material assigned to the Material Dynamic operator, for best results, use a total of 65,536 particles or fewer.

Reset Particle Age—When on, sets each particle’s age to 0 when it enters the event.

When using an animated material with a Bitmap map, turn this on to ensure that the animation always plays from the first frame.

Randomize Age Offset—When on, the software varies the difference between the particle age and the starting material ID at random. The maximum difference is determined by the Max Offset parameter.

Max Offset—The maximum number of frames by which the software can randomly vary particle age.

Sub-Material Rotoscoping group
These settings let you choose the basis on which the operator changes material ID assignments when using a compound material such as Multi/Sub-Object, and specify the rate of change.

Material ID—Assigns the same material ID to all particles. Use the numeric field to set the ID value.

Cycle—Assigns each particle a material ID in the range 1 to N, where N=# Sub-Materials, in increasing sequential order. The first ID assigned is 1, then 2, continuing to increment each by 1 until N; then 1 again, and so on.

Random—Assigns each particle a random material ID in the range 1 to N, where N=# Sub-Materials.

# Sub-Materials—The highest ID number assigned to particles using the Cycle or Random option.

In general, set this to the same number of sub-materials in the Multi/Sub-Object material. If you set it to a smaller number, the operator will use only that many sub-materials, starting with the first and counting upward.

Note: The software automatically sets this value to the number of sub-materials in the material, once only, the first time you apply the material to the operator. Any subsequent changes in the material itself, or applying a different material to the operator, will not change or update the setting.

Rate Per Sec(ond)—Sets the number of times per second that the assigned material ID is incremented. If this value is the same as the rate at which particles enter the event, then one ID is
assigned per particle. If it’s lower, then multiple particles are given the same ID, or if it’s higher, then the software increments the assigned ID faster than 1 per particle.

For instance, if particles enter the event at intervals of 1/60 of a second, and Per Second=30, then each pair of particles will be assigned the same ID. Or if particles enter the event at intervals of 1/15 of a second, and Per Second=30, then the ID is incremented (or changed randomly) twice per particle.

Loop—When on, and the last ID has been assigned, the software loops back around to the first ID and continues the cycle. When off, the software assigns the last cycle ID to all subsequent particles. Available only with the Cycle assignment method. Default=off.

For example, say you want the first eight particles that enter the event to use different materials, and all subsequent particles to use a ninth material. To do so, you would create a nine-sub-material Multi/Sub-Object material and assign it to the Material Dynamic operator. Choose the Cycle assignment method, and set # Sub-Materials=9. Set the Rate Per Sec value to the rate at which particles enter the event. Lastly, turn off Loop.

Sync By—Choose the time frame for applying animated parameters. Available only with the Material ID and Cycle options.

• Absolute Time—Any keys set for parameters are applied at the actual frames for which they’re set.

• Particle Age—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.

• Event Duration—Any keys set for parameters are applied to each particle starting when it first enters the event.

Rand Offset—When on, the software varies the difference between the particle age and the assigned material ID at random. The maximum difference is determined by the numeric parameter. Available only with the Material ID and Cycle options.

Uniqueness group

The Uniqueness setting varies the sequence of assigned IDs with the Random option, and the offset with the Randomize Age Offset option.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

Mapping Operator

The Mapping operator lets you assign a constant UVW mapping to the entire surface of the particles. It works in conjunction with a map specified in a material operator in the current event. By animating the mapping coordinates, you can vary the location on the material map from which the particle color is taken, thus changing the particle color in a predictable way over time.

The Mapping operator was designed primarily to be used with gradient maps, although you can use it with any map you like. The procedure below describes a recommended method for using the Mapping operator.

See also

Material Static Operator (page 2–187)

Material Frequency Operator (page 2–189)

Material Dynamic Operator (page 2–191)
**Procedure**

*Example: To animate particle coloring using the Mapping operator:*

1. Open the Material Editor, and create a material that uses Gradient Ramp as the Diffuse map.
2. On the map’s Gradient Ramp Parameters rollout, make sure Gradient Type is set to Linear.
3. Create a colorful gradient. The Mapping operator uses the colors in left-to-right order as the U value increases from 0.0 to 1.0.
4. Add a Particle Flow Source object to the scene.
5. Open Particle View.
6. In Event 01, click the Speed operator and set Speed to 100.
7. In Event 01, click Display and set Type to Geometry.
8. Add a Material Static operator to Event 01, and then click the operator in the event.
9. Drag the material you created from its Material Editor sample slot to the button (labeled “None”) on the Material Static parameters rollout in Particle View.
10. Add a Mapping operator to Event 01, and then click the operator in the event.
11. On the Mapping rollout in Particle View, turn on Show Map In Viewport.
12. Go to frame 100 and turn on Auto Key.
13. On the Mapping rollout in Particle View, set Map Values > U=1.0.
14. For Sync By, choose Particle Age.
15. Turn off Auto Key, and click Play Animation.

As each particle is born and falls, its U mapping coordinate gradually changes from 0.0 to 1.0, while its color changes to match the corresponding position across the Gradient Ramp map.

To vary the effect, try changing the Gradient Type setting, and animate the V and W values as well. Or, for more sophisticated effects, assign animation controllers such as Noise Float to the Mapping coordinate values, or wire them to other changing parameters in the scene (Animation menu > Wire Parameters > Parameter Wire Dialog).

**Tip:** In the Material Editor, it’s easier to see the result of the Gradient Type choice if you set Sample Type to Cube.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Map Values group**

- **U/V/W**—Set the coordinates on the map from which the particle color is taken. One pixel from this location is used to color the entire particle.

In general, U and V represent the horizontal and vertical dimensions, respectively, beginning at the
upper-left corner of the map, and W is useful only with three-dimensional maps, in which context it specifies depth.

**Sync By**—Choose the time frame for applying animated parameters. For further information, see *Animation Offset Keying group (page 2–158).*

- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
- **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.

**Channel group**

The Channel setting determines whether the mapping is applied to a map channel or to a vertex color channel.

- **Map Channel**—The mapping is applied to the specified map channel.
- **Vertex Color Channel**—The mapping is applied to the particles’ vertex color channel.

**Show Map In Viewport**—The map coloring is visible in the viewports.

---

**Additional Operators**

**Cache Operator**

*Particle View (page 2–125) > Click Cache in an event or add a Cache operator to the particle system and then select it.*

The Cache operator records and stores particle states to memory. When it’s in effect, the first time you play or go to a frame, the particle motion up to and including the frame is calculated and recorded in the cache. Thereafter, playing the frame or any previous frames uses the data in the cache, rather than recalculating the particle action. This is particularly useful with large or complex particle systems, where playback, and particularly backtracking, are slow because of the large amount of processing required. With caching on, the particle system needs to be calculated only once for each frame, and thereafter playback and moving among frames is significantly faster.

To cache an entire flow, add a Cache operator to the global event. To cache an individual local event, add a Cache operator to it.

To determine how best to implement caching in your particle system, turn on Particle View > Track Update > Update Progress, and then play the animation or go to a frame relatively distant from the current frame. Observe the particle diagram, and watch for events with actions that highlight longer than a fraction of a second, or events with more activity than the rest. Any such events could benefit from caching.

Note: Use no more than one Cache operator per event, unless you’re using two: one set up for viewports, and the other for rendering. Similarly, don’t use global and local Cache operators in the same flow, unless one is set up for viewports, and the other for rendering.

Tip: When using real-time playback, if playback isn’t fast enough, you can use the Cache operator to speed it up. For best results, set the Viewport integration step to the same value as the real-time playback speed, and set cache sampling to Integration Step. For example, if the real-time playback speed is set to 1/4x, then the Viewport Integration Step for viewport should be also set to 1/4 Frame, and the Cache operator Sampling parameter should be set to Integration step.

Thus, because real-time playback is showing four
times as many frames per second, and the Cache operator has stored four times as many frames per second, the two are synchronized. If the real-time playback speed is set to 2x or 4x, set the Viewport Integration Step to Frame.

**Procedure**

**Example: To use the Cache operator:**

1. Start or reset the software, and then add a Particle Flow system.
2. Open Particle View.
3. In Particle View, go to Options menu > Track Update and turn on Update Progress.
   This lets you monitor calculation of the particle system by highlighting actions in Particle View as the system executes them.
4. In Particle View, Add a Keep Apart operator (page 2–172) to Event 01.
   Keep Apart is a fairly calculation-intensive operator.
5. Go to frame 100 by clicking the right end of the time slider track.
   There is a delay as the system calculates all particle motion between frames 0 and 100. This is necessary because Particle Flow is a history-dependent system. At the same time, the actions in the system highlight briefly in Particle View as they’re executed at each frame.
6. Go to frame 50 by clicking the center of the time slider track.
   There is another delay as the system calculates all particle motion between frames 0 and 50.
7. In Particle View, drag a Cache operator from the depot to Event 01. Insert it anywhere in the event.
   When you release the mouse button, there is a delay as the Cache operator automatically caches particle motion from the start of the animation to the current frame. Meanwhile, each action highlights briefly at each frame.
8. Go to frame 20 or so.
   The only operators that highlight are Cache (very fast) and Display; there is no delay for calculation. All frames between 0 and 50 have been cached.
9. Go to frame 100.
   The delay this time is a result of caching particle motion for frames 50 to 100.
10. Jump to different frames, and drag the time slider.
   All particle motion is now cached, so no delays occur. But if you change a setting’s value, the Cache operator automatically recalculates and stores the particle motion.
11. Go to frame 100, and then, in Particle View, click the Keep Apart operator and use the keyboard to change the Falloff Zone value to 8.0.
   By default, the Cache operator automatically updates the cache when you change any parameters it stores. Thus, when you change the Falloff Zone value at frame 100, it recalculates and recaches the entire animation.
12. Click the Cache operator and set Update to Manually.
   The Cache operator no longer updates the stored data automatically when you change a parameter.
13. Click the Keep Apart operator, change the Falloff Zone value to 9.0, and then drag the time slider.
   There is no delay, because the animation is still playing back from the cached data. However, the cached data is now invalid, because you changed a parameter in the particle system.
Click the Cache operator, and in the Manual Update group, click Update. The software closes Particle View, updates the cache for the active segment, and then reopens Particle View. The cached data is now accurate.

Other manual update options let you update the cache for the entire animation or a custom frame range.

As you can see, the Cache operator is quite powerful. When present and active, by default it overrides recalculation of the particle system, except when you change any action parameters, whereupon it automatically updates the cached data. Used appropriately, it can save a good deal of time in setting up and testing particle systems.

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Use At**—Caches particle motion when playing back in the viewports, or at render time, or both. Default=Viewport.

**Important**: Choose the Viewport/Render option only when using the same number of particles in the viewports and for rendering (see *Quantity Multiplier group* (page 2–137)). Otherwise, unpredictable results can occur.

**Update**—If you change a parameter in the particle system, the cached data might become invalid.
This setting determines whether Particle Flow should update the cache automatically, or let you do it manually. Default=Always.

- **Always**—Changing any parameter under the Cache operator’s purview causes it automatically to update stored data from the start of the current range (see next parameter) to the current frame.
- **Manually**—Updating occurs only when you click the Update button, or clear the cache and then move to a different frame.

**Range**—Sets the frame range within which the Cache operator operates. Default=Active Segment.

- **Complete**—The software caches the entire animation.
- **Active Segment**—The software caches only frames in the active segment, as defined by the Start Time and End Time settings on the Time Configuration dialog. This is the frame range shown on the track bar. You can also change the active segment by holding down [Alt] and [Ctrl] and dragging the track bar with the left, middle, or right mouse button.
- **Custom**—The software caches only frames in the custom range, as defined by the Cache operator’s Start Time and End Time settings (see following).

  **Note:** If you cache only part of the animation, Particle Flow calculates particle behavior in subsequent, non-cached frames using the cached data. For example, if you cache frames 0 to 50, and then jump to frame 60, Particle flow will calculate frame 51 based on the cached data, and frames 52 to 60 based on each previous frame.

**Start/End Time**—The first and last frames of the range considered for caching when Range=Custom (see above). Default=0, 30.

  **Note:** The frame range time frame is in absolute time; that is, in terms of the entire animation. If you use a Cache operator locally, and specify a frame range during which no particles are present in the event, Particle Flow won’t use the cache.

**Sampling**—Determines how often the Cache operator samples and caches the animation. Default=Every Frame.

- **Every Frame**—The software caches animation data once per frame.
- **Integration Step**—The software caching animation data at each integration step, using the Integration Step setting as specified in the Use At setting (see above). If Use At is set to Viewport/Render, it uses lower of the two Integration Step values. For example, if Viewport is set to Half Frame, and Render to 1/8 Frame, the sampling rate would be eight per frame.
- **Every Nth Frame**—The software caches animation data at frame intervals specified by the N value, below.

**N**—Determines the frame interval for caching when Sampling (above) is set to Every Nth Frame. Default=5.

  For example, with N set to the default value of 5, the cache stores animation data for every fifth frame.

**Cache Test Results**—When caching particle data, this caches the results of test actions as well. Default=on.

  This is important if Cache is used as a local operator, and the next event doesn’t have a Cache operator. For the next event to work properly, it should receive particles from the current event. Those particles result from the activity of a test action. The Cache operator can record the test activity to play it back later.

  If the Cache operator is used as a global operator, there is no need to cache the test results. This is because the system has cache data for every event,
and is able to jump to an arbitrary frame without
the need for test results.

**Save Cache with File**—When on, the software
Includes the cached data with scenes that you save
to disk. This can significantly increase the size
of saved files, but saves the time of recalculating
the particle motion upon reloading the file.
Default=off.

Normally, the cache data is saved only in disk
files that you create with the Save or Save As
commands. You can also instruct the software to
include cached data with other types of files using
the two following options.

**Save Cache with Hold**—Saves cached data in
the Hold file, created with Edit menu > Hold.
Default=off.

**Manual Update group**

These controls let you update or clear the cache
manually within a frame range, or clear the entire
cache.

**Update**—Calculates particle motion within the
current range (defined below) and stores it in
the cache, replacing any existing cached data.
Available only when Range is set to Active Segment
or Custom.

During the update, the software temporarily
closes Particle View and displays a Cache Update
Progress bar, while moving the time slider through
the cached range. At the same time, by default, the
animation plays in the viewports. To prevent this,
and speed calculation, turn off Update Viewports.

If the cache runs out of memory during a manual
update, Particle Flow halts the update operation
and displays an alert. Click OK to continue, and
then, if possible, increase the Limit value before
updating the cache again.

**Clear**—Deletes any cached data.

After you clear the cache buffer, if you go to a
different frame or change any action parameters,
the software automatically caches particle motion
even if Update is set to Manually.

**Range**—Sets the frame range within which the
Cache operator recalculates data when you click
Update. Default=Active Segment.

- **Complete**—The software clears the cache for
entire animation. Choosing Complete makes
the Update button unavailable; this option is for
clearing the cache only.

To update the entire animation, set the active
segment or the custom range to encompass all
frames, and then use the corresponding choice
and click Update.

- **Active Segment**—The software updates the
cache only for frames in the active segment,
as defined by the Start Time and End Time
settings on the Time Configuration dialog. This
is the frame range shown on the track bar. You
can also change the active segment by holding
down [Alt+Ctrl] and dragging the track bar
with the left, middle, or right mouse button.

- **Custom**—The software updates the cache only
for only frames in the custom range, as defined
by the Start Time and End Time settings (see
following).

**Start/End Time**—The first and last frames of the
range that’s updated when Range=Custom (see
above). Defaults=0, 30.

**Update Viewports**—When on, the animation
plays in the viewports during manual updating
of the cache. Turn this off to disable playing
the animation in the viewports during manual
caching; this can speed up the caching process,
especially with large or complex particle systems.
Default=on.
Memory Used (K) group

The Cache operator stores data in system memory; you can specify an upper limit for the amount of memory it uses. If the Limit setting and the amount of cached data exceeds the available free memory, the computer system might use virtual (hard disk-based) memory instead, which slows down the caching. If Particle Flow fills the cache, any remaining frames are calculated on the fly.

This group also lets you monitor the amount of memory used for caching data.

**Limit**—The maximum amount of system memory used to cache particle data, in kilobytes. Default=100,000, or 97.6 MB.

**Total**—The amount of memory currently used by the cached data, in kilobytes. Read-only.

Note: Even animation frames with no particles will probably consume a certain amount of cache memory. The reason for this is that the cache also stores states for randomly calculated values such as Variation, to ensure that particle activity is consistent across a rendering network, and with machines that might not have regular access to all frames.

**Current Frame**—The amount of memory used by the data cached for the current frame, in kilobytes. Read-only.

Display Operator

The Display operator lets you specify how particles appear in the viewports. The default display mode is Ticks, which is the simplest, and thus the fastest to display. It’s useful for animations that use a large number of particles. At the opposite end of the complexity spectrum is the Geometry option, which lets the software depict particles as their actual shapes. In addition, the Display operator provides a variety of simple shapes that provide fast feedback in testing animation, as well as the ability to easily distinguish among particles in different events. It also lets you set the percentage of visible particles.

By default, Particle Flow automatically inserts a new Display operator in each event you add to the system. Alternatively, you can choose Particle View > Options menu > Default Display > Global. With this option, the software automatically inserts a Display operator in new global events, but does not add one to new local events.

Particles in any local event that doesn’t contain a Display operator don’t appear in the viewports, unless an associated global event contains a Display operator (that is, a global Display operator). If a particle is affected by multiple Display operators (for example, both global and local operators) simultaneously, the software generates all viewport particle representations at the same time.

See also

Render Operator (page 2–206)

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Type**—Choose how particles appear in the viewports. The two-dimensional particle markers depict position only. Geometry shows how
particles will actually render, in three dimensions; Lines shows speed and direction of motion; and Bounding Boxes reflects scale and orientation.

In the following list, each choice’s description is preceded by the number of dimensions used by each particle representation:

- **None**—Particles do not appear in the viewports.
- **Dots**—(0D) Each particle appears as a single pixel.
- **Ticks**—(2D) Each particle appears as a + sign.
- **Circles**—(2D) Each particle appears as a small circle.
- **Lines**—(1D) Each particle appears as a line, one pixel thick. The line’s length indicates particle speed, and its orientation reflects the direction of motion. Use this option for fast, accurate feedback when experimenting with the Speed operators.

Tip: When using the Lines display type with the OpenGL display driver, slow-moving particles might not appear properly in the viewports. In such cases, to see all particles, add a second Display operator in the same event and set its Type to Dots.

- **Bounding Boxes**—(3D) Each particle appears as a bounding box. Use this option for a good representation of the final animation, at a slight cost in computational speed.
- **Geometry**—(3D) Each particle appears as its actual geometry. Use this option for the best representation of the final animation, at the greatest cost in computational speed.
- **Diamonds**—(2D) Each particle appears as a diamond.
- **Boxes**—(2D) Each particle appears as a small square.
- **Asterisks**—(2D) Each particle appears as an asterisk (*).

- **Triangles**—(2D) Each particle appears as a small triangle.

**Visible %**—Specifies the percentage of particles visible in the viewports. This option lets you speed up viewport redrawing by reducing the number of visible particles.

**Show Particle IDs**—When on, each particle’s unique index number is visible in the viewports. Particles are numbered in the order of their birth, starting with 1 for the first particle born.

**[color swatch]**—Shows the color for particles displayed using options other than Geometry, as well as for the particle IDs. The software chooses a different color at random for each Display operator added to the system. In addition to the Type options, using different colors helps to distinguish among particles in different events.

To change the color, click the color swatch and use the Color Selector dialog to choose a new color.

If a system has a global Display operator, and you select its Source icon in a viewport, then you can change the color of the global Display operator from the color swatch on the Modify panel. However, changing the global Display operator’s color in Particle View does not change the color of the swatch on the Modify panel.

Note: When a Particle Flow source icon is selected, all of its non-selected particles, other than those shown as geometry, are colored white in the viewports. To see all assigned particle colors, deselect the particle system.

**Selected**—Choose how selected particles (page 2–138) appear in the viewports. The choices are the same as for Type, above.
Chapter 11: Space Warps and Particle Systems

Force Operator

Particle View (page 2–125) > Click a Force operator in an event or add a Force operator to the particle system and then select it.

The Force operator lets you influence particle motion with one or more space warps from the Forces category. Use this operator along with different forces to simulate the effects of wind, gravity, and so on. The following force space warps work with the Force operator:

- Displace (page 2–76)
- Drag (page 2–66)
- Gravity (page 2–73)
- Motor (page 2–61)
- PBomb (page 2–68)
- Push (page 2–59)
- Vortex (page 2–63)
- Wind (page 2–75)

Note: By default, the influence of these space warps on Particle Flow particles is equivalent to their influence on the 3ds Max 2 particle systems: PArray, Super Spray, Blizzard, and PCloud. To obtain an influence on Particle Flow particles equivalent to that of the 3ds Max 1 particle systems Snow and Spray, set Influence to 100.0.

Tip: To make the particles follow a path, use the Speed By Icon operator (page 2–162) and use Path Constraint to assign its icon to the path. For a procedure, see Example: To send particles along a path: (page 2–163).

To employ deflectors for particle dynamics, with or without the Force operator, use the Collision test (page 2–212) and Collision Spawn test (page 2–215).

Procedure

To affect particle motion with force space warps:

1. Add one or more force space warps to the scene, and set them up as necessary.
2. In Particle View, add a Force operator to any events in which particles are to be affected by the forces. To affect particles in all events, add the Force operator to the PF Source instead.
3. Highlight the Force operator, and then use the Add or By List button to apply the force space warps to the operator.

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

Force Space Warps group

This group displays the forces currently in effect, and let you add and remove forces.

[List]—Shows the forces that apply to this operator. If more than three forces apply, a scroll bar appears at the right side of the list.
If you delete a listed space warp from the scene, its name is replaced in the list by the entry “<deleted>”.

Note: Particle Flow applies the forces to particle motion in the order in which the space warps appear in the list; the effect is cumulative in top-to-bottom order. First, the topmost space warp is applied to particle motion, then the second space warp is applied to the result of the first space warp, and so on. Changing the order can alter the final result.

Add—Click this button, and then select a force space warp in the scene to add it to the end of the list.

By List—Click this button, and then use the Select Force Space Warps dialog to add one or more space warps to the list. The space warps must already exist in the scene.

The software adds space warps to the list in same order in which they appear in the dialog. To effect a different order, use the Add button to add them one at a time.

Remove—Highlight a space warp in the list, and then click this button to remove it from the list. Any removed space warps remain in the scene.

Force Field Overlapping—Determines how multiple forces that occupy the same volume of space affect the particles. With Additive, the forces are combined according to their relative strengths. With Maximum, only the force with the greatest strength affects the particles.

For example, you might apply Wind and Gravity space warps to particles, and set their Strength parameters to 1.5 and 1.0, respectively. If you choose Additive, the Wind space warp will have approximately 50 percent more influence over the particles than the Gravity space warp. But if you choose Maximum, only the Wind space warp will affect the particles.

Influence—Specifies the strength with which the force or forces are applied to the particles as a percentage. Default=1000.0.

A negative Influence value reverses the force effects.

Note: By default, the influence of the Force space warps on Particle Flow particles is equivalent to their influence on the 3ds Max 2 particle systems PArray, Super Spray, Blizzard, and PCloud. To obtain an influence on Particle Flow particles equivalent to that of the 3ds Max 1 particle systems Snow and Spray, set Influence=100.0.

Offset Influence group

Choose the time frame for applying animated parameters. For an explanation, see Animation Offset Keying group (page 2–158).

Sync By—Choose the time frame for applying animated parameters:

- Absolute Time—Any keys set for parameters are applied at the actual frames for which they’re set.
- Particle Age—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- Event Duration—Any keys set for parameters are applied to each particle starting when it first enters the event.

Script Wiring rollout

This rollout appears in the parameters panel below the main operator rollout after you highlight the operator, right-click it, and then choose Use Script Wiring. Thereafter, a check mark appears next to the Use Script Wiring in the right-click menu, and the rollout appears whenever you highlight the operator. To turn off script wiring, choose Use Script Wiring again from the right-click menu.
Script wiring lets you use a script to control parameters that you normally specify in the operator’s parameters. Place a Script operator (page 2–208) before the Force operator in the event, and then use it to define values in the particleFloat channel. You’ll find an example script below.

**Use Script Float As**—Choose either of the following:

- **Not Used**—Particle Flow uses the Influence setting specified in the Parameters rollout.
- **Influence**—Particle Flow applies the script to the Influence setting.

**particleFloat Sample Script**

Note: See this topic in the online User Reference for the particleFloat sample MAXScript code.

---

**Notes Operator**

*Particle View (page 2–125)* > Click Notes in an event or add a Notes operator to the particle system and then select it.

The Notes operator lets you add a textual comment to any event. It doesn’t have any direct effect on the particle system, but it helps you keep track of the overall function of each event.

Note: You can also add a comment directly to an event or action by right-clicking it and choosing Comments.

---

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

The interface is a simple text box. Click in the box and enter your text.

---

**Render Operator**

*Particle View (page 2–125)* > Click a Render operator in an event or add a Render operator to the particle system and then select it.

The Render operator provides controls related to rendering particles. You can specify the form that rendered particles are to take, and how to convert the particles to individual mesh objects for rendering purposes.
The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Type**—Lets you render particles as bounding boxes or geometry, or disable the particle system at render time, or enable the particle system but prevent it from sending renderable particles to the 3ds Max renderer. Default=Geometry.

- **None**—The particle system (or event, if used locally) is considered non-renderable, and therefore is never evaluated during render.
- **BoundingBox**—Particles render as boxes whose sizes represent the particle geometry extents. Use this option with complex particle systems to speed up test renders.
- **Geometry**—Particles render with their actual geometry. Use this option with simpler particle systems, and for the final render.
- **Phantom**—Use this option when you want Particle Flow to function normally, calculating the animation at each frame, but not to render geometry directly. An example would be when you’re using a *Final Step Update script* (page 2–140) to pass data from the particle system to other objects in the scene.

**Visible %**—The percentage of particles that render. Range=0 to 100. Default=100.

Lower this value for faster rendering of complex particle systems.

You can also reduce the number of particles in the system at render time with the *Quantity Multiplier > Render setting* (page 2–137).

**Render Result group**

These settings determine how the system converts particles to mesh format for rendering. By default, the software renders all particles as a single mesh per event, which provides for the most efficient operation under most conditions. However, in some situations each particle should be converted to an individual mesh object by turning on Mesh Per Particle. For example, with particles each of whose face count exceeds 10,000, it’s most efficient to render a mesh per particle. Alternatively, you can opt to combine particles into multiple meshes by specifying a face count and number of particles per mesh.

Certain renderers might require a non-default setting for Render Result. Consult the renderer documentation for further information.

Note: The number of particles Particle Flow can handle per frame is limited only by system resources, but each single mesh is allowed a maximum of 5,000,000 faces or vertices. If the total number of faces or vertices in a mesh exceeds 5,000,000, Particle Flow ignores particles beyond this limit.

- **Single Mesh**—Sends the renderer one mesh object comprising all particles in the system.
- **Multiple Meshes**—Sends the renderer the specified number of mesh objects, each containing the specified number of particles. If the result of dividing the total number of particles by the Particles p/Mesh value is less than the specified Mesh Count value, some of the meshes might contain few or no faces.
This is a compromise method of operation, and can be used with renderers that cannot handle all particles in a single mesh, but can deal with groups of particles of a certain size.

**Mesh Count**—The maximum number of mesh objects that Particle Flow will send to the renderer.

**Particles p/Mesh**—The number of particles that each mesh object will comprise.

**Mesh Per Particle**—Sends the renderer a separate mesh for each particle.

This is the least efficient method of operation, but might be required by certain renderers.

**Note:** With the default scanline and mental ray renderers, this method does not support rendering of particles born after the start of the rendered frame sequence. Generally, use **Mesh Per Particle** only with renderers that require it.

---

**Script Operator**

The Script operator enables control of particles within the Particle Flow system using a MAXScript script. The script can use any program functionality available to MAXScript.

When you add a new Script operator, it contains a default script that slows particles, and then, when they are slow enough, splits off the first 50 particles into a stream traveling in a negative direction on the world X axis, and the remainder traveling in the opposite direction.

**Tip:** You can use MAXScript to align particle scale with the underlying bitmap, thus providing a "scale bitmap" function. This requires a sandwich with three operators: two Script operators, and a Speed By Surface operator in between. The first Script operator reads the current speed vector into the MXVector channel, thus caching the current speed. The Speed By Surface operator changes the speed according to the underlying bitmap. And the second Script operator reads the speed channel into a temporary variable, restores the speed from the MXVector channel (the cached value), and uses the temporary variable to define the scale. This way, the original speed is restored, and the scale value is defined by the bitmap.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Edit Script**—Click this button to open the current script in a MAXScript Editor window.

For detailed information about the MAXScript utility, open the MAXScript Reference, available from Help menu > MAXScript Reference.

**Uniqueness group**

The Uniqueness setting provides a randomization seed that the script can use or ignore.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Flows**

The flows category contains two operators for creating initial particle system setups. These are:
Empty Flow provides a starting point for a particle system consisting of a single global event containing a Render operator. This lets you build a system completely from scratch, without having first to delete the default operators provided by the Standard Flow system.

To use Empty Flow, drag it from the depot to the event display. In Particle View, this creates a global event containing a single Render operator. If the Global default display option is active in the Particle View > Options menu, the global event will also contain a Display operator. Adding an Empty Flow also creates a Particle Flow Source icon in the viewports, at the world origin (0,0,0).

Note: If an orthogonal viewport is active when you add an Empty Flow to the system, the software orients the new source icon parallel to the plane of the active viewport, with the default emission direction pointing forward. For example, if the Front viewport is active, the icon is oriented parallel to the XZ plane in the world coordinate system, with the default emission direction along the positive Y axis. If a Camera or Perspective viewport is active, Particle Flow uses the default orientation: parallel to the XY plane, pointing in the negative Z direction.

See also
Standard Flow (page 2–209)

Standard Flow provides a starting point for a particle system consisting of a global event containing a Render operator, wired to a birth event containing a Birth, a Position, a Speed, a Rotation, a Shape, and a Display operator, with all parameters set to default values. This is the same system that the software creates automatically when you add a Particle Flow icon to the viewport.

To use Standard Flow, drag it from the depot to the event display. In Particle View, this creates the particle system described above. If the Global default display option is active in the Particle View > Options menu, the global event will also contain a Display operator. Adding a Standard Flow also creates a Particle Flow Source icon in the viewports, at the world origin (0,0,0).

Note: If an orthogonal viewport is active when you add a Standard Flow to the system, the software orients the new source icon parallel to the plane of the active viewport, with the default emission direction pointing forward. For example, if the Front viewport is active, the icon is oriented parallel to the XZ plane in the world coordinate system, with the default emission direction along the positive Y axis. If a Camera or Perspective viewport is active, Particle Flow uses the default orientation: parallel to the XY plane, pointing in the negative Z direction.

Empty Flow (page 2–209)
Tests

The basic function of a test in Particle Flow is to determine whether particles satisfy one or more conditions, and if so, make them available for sending to another event. When a particle passes a test, it is said to “test True.” To send eligible particles to another event, you must wire the test to that event. Particles that don’t pass the test (“test False”) remain in the event and are repeatedly subjected to its operators and tests. Or, if the test isn’t wired to another event, all particles remain in the event. You can use several tests in an event; the first test checks all particles in the event, and each test after the first checks only particles that remain in the event.

One test, Spawn, doesn’t actually perform a test, but simply creates new particles from existing ones, and sets the new particles’ test result to True so they’re automatically eligible for redirection to another event. And the Send Out test simply sends all particles to the next event by default.

Some tests can also serve as operators, in that they contain parameters that modify particle behavior. If you don’t wire a test to another event, it functions only as an operator; the test aspect doesn’t affect particle flow.

Tip: Always place a test at the end of its event, unless you have specific reasons for placing it elsewhere. That way, all preceding actions can take effect during each integration step before the test is evaluated.

All the tests are grouped together in the Particle View depot, and are listed in alphabetical order. All test icons are the same: a yellow diamond containing a simplified diagram of an electrical switch.

The Particle Flow tests in the Particle View depot

The tests are:

- Age Test (page 2–211)
- Collision Test (page 2–212)
- Collision Spawn Test (page 2–215)
- Find Target Test (page 2–218)
- Go To Rotation Test (page 2–224)
- Scale Test (page 2–227)
- Script Test (page 2–229)
- Send Out Test (page 2–230)
- Spawn Test (page 2–230)
- Speed Test (page 2–233)
- Split Amount Test (page 2–234)
- Split Selected Test (page 2–235)
- Split Source Test (page 2–236)

Operators (page 2–142)
Flows (page 2–208)
Age Test

**Particle View (page 2–125) > Click Age Test in an event or add Age Test to the particle system and then select it.**

Age Test lets the particle system check whether a specific amount of time has passed since the start of the animation, or how long a particle has existed, or how long a particle has been in the current event, and branch accordingly.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

The first interface element is a drop-down list that lets you choose the type of age to test. Default=Particle Age.

- **Absolute Age**—Tests the current frame number in the animation.
- **Particle Age**—Tests the current age of each particle in frames. This is the default test type.
- **Event Age**—Tests the current duration of the current event in frames.

**Test True If Particle Value**—Lets you specify whether the test passes particles on to the next event if the test succeeds or fails. Default=Is Greater Than Test Value.

By default, Age Test returns True if the value tested for exceeds the Test Value quantity, but you can alternatively choose Is Less Than Test Value. For example, if you use the Absolute Age test type and set Test Value=60 and Variation=0, and choose Is Less Than Test Value, then particles will move to the next event only until frame 60. After frame 60, any remaining particles stay in the current event unless another test returns True.

**Test Value**—The specific frame number, particle age (in frames), or event duration (in frames) to test for. Default=30.

This value cannot be animated.

**Variation**—The number of frames by which the value tested for can vary randomly. Default=5.

This value cannot be animated.

To obtain the actual test value for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Test Value setting. For example, if Test Value=300 and Variation=10, then tested value for each particle would be between 290 and 310.

**Subframe Sampling**—Turning this on helps avoid particle "puffing" when passing particles to the next event by testing the time at a much higher subframe resolution (that is, throughout each frame), rather than using the relatively coarse frame resolution. Default=on.

"Puffing" is the effect of creating separate "puffs" or clusters of particles, rather than a continuous stream.

Turn off Subframe Sampling to cause the test to be executed exactly at frame times.
Uniqueness group

The Uniqueness setting enables randomization of the test value variation.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Collision Test**

*Particle View (page 2–125) > Click Collision in an event or add Collision to the particle system and then select it.*

Collision tests for particles that collide with one or more specified Deflector space warps. It can also test whether a particle has slowed down or sped up after one or more collisions, has collided more than once, and even whether it will collide with a deflector in a specified number of frames.

The Collision test supports all deflector space warps except the DynaFlect deflectors:

- **POmniFlect (page 2–78)**
- **SOmniFlect (page 2–84)**
- **UOmniFlect (page 2–85)**
- **SDeflector (page 2–87)**
- **UDeflector (page 2–89)**
- **Deflector (page 2–90)**

Tip: When testing for collisions with multiple deflectors, for best results, place all the deflectors in a single Collision test. This tests for collisions with all the deflectors simultaneously, and helps avoid possible missed collisions.

---

**Procedure**

**Example: To test for particles slowing down after one or more collisions:**

In the real world, particles bouncing repeatedly against a surface lose kinetic energy at each collision, and slow down gradually. Rather than testing for a specific number of bounces, you can use the Is Slow After Collision(s) to test whether particle speed has sunk below a specific level.

1. Start or reset 3ds Max. Set the animation length to **500** frames.
2. Add a Gravity space warp and a Deflector space warp. Decrease the deflector’s Bounce setting below 1.0, and increase the Variation and Chaos value above 0.0. Set the deflector’s Width and Length to **500**.
3. Create a default Particle Flow system. Position the emitter directly above the deflector.
4. Add a **Force operator (page 2–204)** to the end of Event 01 and add the Gravity space warp to the Force operator.
5. Create a new event with a **Display operator (page 2–202)**, and change the display type to a different choice than is used in Event 01.
6. Add a Collision test to Event 01, below the Force operator, and wire it to the new event.
7. In the Collision test settings, add the deflector. Choose Is Slow After Collision(s), and set Speed Min=**100** (assuming you’re using the default initial speed of 300).
8. Play the animation. You might need to adjust one or more settings before seeing the expected behavior.

After several bounces, the particles change in appearance and move steadily away from the deflector, indicating that they’ve entered the second event. Of course, you can set any behavior you like in this event.

**See also**

*Collision Spawn Test (page 2–215)*
In the next step, you’ll see what happens when actions in an event are not in the right order.

9. In Event 01, move the Collision test above the Force operator, and then play the animation. Quite a few particles leak through the deflector. This happens because the software first tests the particles for a collision, and then applies the Gravity force. The particles that are approaching the deflector and are very close to it are being tested for a collision, which tests False because they haven’t actually struck the deflector yet. The software then applies the gravity, which pushes them past the deflector, making them no longer eligible for testing for collision. Generally speaking, it is best to keep Force operators above Collision tests in each event to ensure that particles don’t leak through the deflector.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Deflectors group**

This group displays the deflectors currently in effect, and let you add and remove deflectors.

- **[list]**—Shows the deflectors that apply to this operator. If more than three deflectors apply, a scroll bar appears at the right side of the list.

  If you delete a listed space warp from the scene, its name is replaced in the list by the entry “<deleted>”.
Add—Click this button, and then select a Deflector space warp in the scene to add it to the list.

By List—Click this button, and then use the Select Deflectors dialog to add one or more space warps to the list. The space warps must already exist in the scene.

Remove—Highlight a deflector in the list, and then click this button to remove it from the list. Any removed space warps remain in the scene.

Test True If Particle group
Choose the condition under which the test will pass particles on to the next event, and then adjust the associated setting or settings. Default=Collides.

Collides—Choose this option, and then set Speed according to how particle speed should be affected by the collision.

Speed—Choose one of the following. Default=Bounce.
- Bounce—The speed and direction after collision is determined by the deflector properties.
- Continue—Particle speed and direction are unaffected by the collision.
- Stop—Particle speed is set to 0 after the collision.
- Random—Particles bounce off the deflector in random directions.

Is Slow After Collision(s)—The test succeeds if, after collision, particle speed is less than the Speed Min value.

With this choice, particle behavior with respect to the deflector(s) is the same as with the Collides > Bounce option.

Speed Max—Particles traveling faster than this speed, in system units per second, test True and become eligible for moving to the next event. Default=1000.0.

Collided Multiple Times—The test becomes True after a particle collides a specific number of times. The particle is moved to the point of the last collision and then redirected to the next event.

# Times—The number of times a particle must collide in order to test True.

Speed—Determines speed and direction after the specified number of collisions. See above for explanations of the choices.

Will Collide—The software extrapolates particle motion in a linear fashion, based on the current direction and speed, and the test becomes True if the results suggest that the particle will collide with the deflector during a specified time interval. The particle is redirected to the next event without updating its speed or position.

# Frames—The number of frames ahead during which the software looks for an impending collision.

Uniqueness group
The Uniqueness setting enables randomization of the Random options in the Speed drop-down lists.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.
Collision Spawn Test

Particle View (page 2–125) > Click Collision Spawn in an event or add Collision Spawn to the particle system and then select it.

Collision Spawn creates new particles from existing ones that collide with one or more Deflector space warps. You can specify different post-collision behavior for the colliding particles and their offspring. Each spawned particle is born at the same location as its parent, and has the same orientation and shape. Collision Spawn can give the spawned particles a different speed and scaling factor. If you wire the Collision Spawn test to another event, spawned particles are sent to that event, where you can specify different properties for the new particles.

Examples of Collision Spawn usage include marks or explosions resulting from collisions between particles and objects. To achieve these effects, you can use Collision Spawn in conjunction with the Shape Mark (page 2–183) and Shape Facing (page 2–176) operators.

The Collision Spawn test supports all deflector space warps except the DynaFlect deflectors:

- POmniFlect (page 2–78)
- SOmniFlect (page 2–84)
- UOmniFlect (page 2–85)
- SDeflector (page 2–87)
- UDeflector (page 2–89)
- Deflector (page 2–90)

Tip: When testing for collisions with multiple deflectors, for best results, place all the deflectors in a single Collision Spawn test. This tests for collisions with all the deflectors simultaneously, and helps avoid possible missed collisions.

See also

Collision Test (page 2–212)
The user interface appears in the parameters panel, on the right side of the Particle View dialog.

In the context of Collision Spawn, a parent is the original particle from which new particles are spawned.

Test True for group

These check boxes let you specify which particles, if any, should become eligible for redirection to the next event upon satisfaction of the test conditions.

Note: After a particle tests True, the Collision Spawn test no longer tests the particle for collision. If you simply want particles to spawn every time they collide, turn either or both of these off and use a different test for redirection.

Parent Particles—When on, parent particles qualify for redirection when the test conditions are met. Default=on.

When using the Spawn On First Collision option, Parent Particles is available only when Delete Parent is off.

This option is also available when using the Spawn On Each Collision option. In this case, parent particles test True only after colliding the number of times specified by the Until # value.

Spawn Particles—When on, spawned particles qualify for redirection when the test conditions are met. Default=on.

Deflectors group

This group displays the deflectors currently in effect, and let you add and remove deflectors.

[list]—Shows the deflectors that apply to this operator. If more than three deflectors apply, a scroll bar appears at the right side of the list.

If you delete a listed space warp from the scene, its name is replaced in the list by the entry “<deleted>”.

Seed: 12345
Collision Spawn Test

**Add**—Click this button, and then select a Deflector space warp in the scene to add it to the list.

**By List**—Click this button, and then use the Select Deflectors dialog to add one or more space warps to the list. The space warps must already exist in the scene.

**Remove**—Highlight a deflector in the list, and then click this button to remove it from the list. Any removed space warps remain in the scene.

**Spawn Rate And Amount group**

Use these settings to specify when particles are to spawn and other values related to how many particles are spawned.

**Spawn On First Collision**—Particles spawn only the first time they collide with a deflector.

**Delete Parent**—When on, deletes each original particle from which a new one is spawned. Available only with the Spawn On First Collision option.

**Spawn On Each Collision**—Particles spawn on each of multiple collisions, up to a limit specified with the Until # parameter.

**Until #**—The maximum number of collisions by the parent particles that produce spawned particles. Available only with the Spawn On Each Collision option. Default=3.

When Test True For > Parent Particles is on, parent particles test True only after colliding the number of times specified by the Until # value.

**Spawnable**—The percentage of particles in the current event that will spawn new particles. This is determined once for each particle, when it enters the event. However, the parameter is animatable. Default=100.0.

For values other than 100.0, Spawnable uses a randomized selection process, which is affected by the Uniqueness Seed value. For example, with five parent particles, Offspring#=1, and Spawnable=80.0, you might get any number of spawned particles between two and five for each collision. The average per spawning would be four, however.

**Offspring #**—The number of new particles the system creates from each parent particle for each spawning event. Default=1.

**Variation**—The amount by which the Offspring # value can vary randomly. Default=0.0.

To obtain the actual test value for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then applies the result as a percentage of the Offspring # setting. For example, if Offspring#=20 and Variation=10, then the actual number of offspring for each particle would be between 18 and 22.

**Sync By**—Choose the time frame to use when animating Offspring # and Variation:

- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
- **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.
- **Restart Particle Age**—When on, sets the age of each newly spawned particle at 0. When off, each spawned particle inherits its parent’s age. Default=on.

**Speed group**

Lets you specify the behavior of spawned particles, as well as their speed in absolute terms or relative to the parents’ speed, with optional random variation. The direction of a spawned particle is always in relation to that of its parent, but you can
set a Divergence so they eventually spread out. Default=Inherited.

**Parent**—Specify the parent’s behavior. Available only when Delete Parent is off.

- **Bounce**—The speed and direction after collision is determined by the deflector properties.
- **Continue**—Particle speed and direction are unaffected by the collision.

**Offspring**—Specify the behavior of the newly spawned particles.

- **Bounce**—The speed and direction of offspring after collision is determined by the deflector properties.
- **Continue**—Speed and direction of offspring are unaffected by the collision.

**In Units**—Choose this to specify the speed of spawned particles in system units per second. Default=100.0.

A positive value inherits the parent’s direction; a negative value reverses it.

**Inherited**—Choose this to specify each spawned particle’s speed as a percentage of its parent’s speed. Default=100.0

A positive value inherits the parent’s direction; a negative value reverses it.

**Variation**—The amount by which a spawned particle’s speed can vary randomly. Default=0.0

To obtain the actual speed for each spawned particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Scale Factor value. For example, if Scale Factor=100 and Variation=20, then each spawned particle would be between 80 and 120 percent of its parent’s size.

**Size group**

**Scale Factor**—The amount of uniform scaling to apply to each spawned particle, as a percentage of its parent’s size. Default=100.0.

**Variation**—The amount by which a spawned particle’s scale can vary randomly. Default=0.0.

To obtain the actual scaling for each spawned particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Scale Factor value. For example, if Scale Factor=100 and Variation=20, then each spawned particle would be between 80 and 120 percent of its parent’s size.

**Uniqueness group**

The Uniqueness setting enables randomization of the Spawnable result, when less than 100.0, as well as of the Variation values.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

**Find Target Test**

By default, Find Target sends particles to a specified target or targets. Upon reaching a target, the particles become eligible for redirection to another event. You can specify that the particles should use a particular speed or time frame in
moving toward the target. You can also specify where on the target the particles should go.

Alternatively, you can use Find Target as a simple proximity test: If a particle comes within a certain distance of its target, it becomes eligible for redirection to the next event.

When you add a Find Target test to the particle system in Particle View (page 2–125), a spherical Find Target icon appears in the scene at the world origin (0,0,0). You can use this icon as a target, or you can use one or more mesh objects in the scene as targets. To display the Find Target parameters on the Modify panel, select the icon. If you delete the icon, the software also deletes the test.

Note: If you add Find Target from the Create panel, Particle Flow creates a separate event for the test in the particle diagram.

Tip: In a particle loop, all particles end up at their respective starting positions, enabling seamless repetition of the resulting animation. You can make particle loops with Particle Flow using a Script operator and a Find Target operator. At the start of the loop, the Script operator should read all particle positions and write them into the MXS Vector channel. Then, at the end of the loop, set the Find Target operator to Control by Time, set Timing to Absolute Time, set Time to the end of the loop, and in the Target group, set Point to By Script Vector. Particle Flow will direct particles to the previously cached position at the specified frame.

The user interface appears in the parameters panel, on the right side of the Particle View dialog.
Control By ...—The drop-down list at the top of the parameters panel lets you choose whether to send particles to a target by specifying the speed and acceleration, or by specifying the amount of time they should take. Alternatively, by choosing No Control, you can test particles’ distance from a target.

- Control By Speed—Specify speed and acceleration settings for the particles to follow while traveling to the target. Use the Control By Speed group to set the parameters.
- Control By Time—Specify time-based settings for the particles to follow while traveling to the target. Use the Control By Time group to set the parameters.
- No Control—With this option, Find Target functions only as a proximity test. When a particle comes within the specified distance of the target, the particles become eligible for redirection to the next event.

Note: When you choose No Control, the Find Target test does not affect particle speed or direction.

Test True If Distance To group
These settings let you choose which distance the Find Target test measures and specify the measured distance. You can choose Target Pivot or Target Point, and specify a distance with the Is Less Than setting.

Target Pivot—Measures the distance between the particle and the target pivot.

If the particles are directed to the outside of the target and the Is Less Than value is small, this condition might never be satisfied.

Target Point—Measures the distance between the particle and the target point.

Is Less Than—When particles are closer than this distance from target pivot or point, they test True and become eligible for redirection to the next event. Measured in scene units.

Note: If you set Is Less Than to 0, the particles might never test True. This might be desirable for an animation of, for example, bees buzzing around a flower but not landing on it. In this case, you might want to use a low value for Accel Limit so the bees don’t circle too close to the flower.

Control By Speed group
Use these settings to specify speed and acceleration parameters when using Control By Speed or Speed Then Time. This group is available only when using Control By Speed.

Use Cruise Speed—When on, the software gives you explicit control over particle speed and speed variation. When off, the software calculates particle speed automatically using the Accel Limit value. Default=on.

Speed—Particle speed in scene units per second. Default=300.0.

Variation—The amount by which the actual Speed value can vary randomly. Default=0.0.

To obtain the actual speed for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then applies the result as a percentage of the Speed setting. For example, if Speed=200 and Variation=10, then the actual speed for each particle would vary randomly between 190 and 210.

Accel Limit—Sets the acceleration limit. This value impacts the inertia and speed of the particles. Default=1000.0.

The default acceleration limit value is based on the default Speed value of 300.0. If you change the Speed value, it is recommended that you also change the Accel Limit value proportionately.

Tip: Use a lower Accel Limit value for smooth motion, and a higher value when greater accuracy
is needed, such as when the particles should hit a small target. You can animate this setting (use Sync By > Event Duration) to specify different appropriate values, depending on the required results.

**Ease In %**—Controls the rate by which particles slow down when it approaches the target point.

The software calculates the final speed with this formula: 
\[(100\% - \text{Ease In}) \times \text{Speed}\]. Therefore, if the Ease In value is 100%, a particle should approach the target with a speed of 0, and if Ease In is 0%, the particle doesn't slow down at all when approaching the target. At intermediate values, the speed is calculated according to the distance to the target point, as linear interpolation between the initial (cruise) speed, and the final speed. When a particle enters the event, the distance to the target point is calculated and later used for the interpolation. Default=0.0.

**Sync By**—Choose the time frame to use when animating Speed, Variation, and Accel Limit:

- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
- **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.

### Control By Time group

![Control By Time](image)

Lets you specify the amount of time particles should take to reach the target.

This group is unavailable when using Control By Speed.

**Timing**—Determines how the software applies the specified timing, defined by the Time and Variation values. The possible options are:

- **Absolute Time**—Time refers to the overall time of the system. Each particle will reach its target at the frame number specified by Time.
- **Particle Age**—Time refers to the time elapsed since the birth of the particle. Each particle will reach its target when its age reaches the value specified by Time.
- **Event Duration**—Time refers to the time elapsed since the particle entered the current event. Each particle will reach its target when it has been in the current for the number of frames specified by Time.

**Time**—The number of frames particles should take to reach the target. Default=60.

**Variation**—The number of frames by which Time can vary randomly. Default=5.

To obtain the actual time to the target for each spawned particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Time.
value. For example, if Time=60 and Variation=20, then the time to target for each particle would be between 40 and 80 frames.

**Subframe Sampling**—Turning this on helps avoid particle "puffing" by timing particles at a much higher subframe resolution (that is, throughout each frame), rather than using the relatively coarse frame resolution. Default=on.

"Puffing" is the effect of clustering particles, rather than producing a continuous stream. This effect is especially noticeable when the emitter is animated.

**Use Docking Speed**—Lets you specify particles' speed when they reach the target.

A particle might be required to reach the target from a specific direction at a specific speed. When Use Docking Speed is off, the software calculates a path for particles to reach the target in the shortest distance with the least acceleration along the path. When Use Docking Speed is on, the software calculates particles' final speed when they reach the target using the Speed and Variation parameters. Therefore if you want a "smooth landing," set Speed to 0.0. Default=off.

**Speed**—The speed of particles when they reach the target in scene units per second. Default=100.0.

**Variation**—The amount by which the actual Speed value can vary randomly. Default=0.0.

**Target group**

By default, Find Target uses its own target icon, but you can use these controls to designate other scene objects as targets instead.

**Icon**—Use the Find Target icon as the target.

Each Find Target test has its own target icon. Even if you don't use it as a target, it still influences particle behavior if you set the docking type to Parallel, Spherical, or Cylindrical.

**Mesh Objects**—Use one or more scene mesh objects as targets. Choose this to make the list and list-management buttons available.

If you designate more than one target, the target used by each particle is determined by the choice in the **Object drop-down list** in this group.

**list**—Shows the mesh objects used as targets. If more than three target objects apply, a scroll bar appears at the right side of the list.

**Add**—Click this button, and then select a mesh object in the scene to add it to the list as a target.

**By List**—Click this button, and then use the Select Target Objects dialog to add one or more mesh objects to the list. The objects must already exist in the scene, and the dialog shows only eligible objects.

**Remove**—To remove a target object from the list, first highlight it and then click this button. Any removed objects remain in the scene.

**Sync By**—Choose the time frame to use when sending particles toward animated objects when using Animated Shape or Follow Target Animation:

- **Absolute Time**—Animation derived from the target is applied to particles immediately.
- **Particle Age**—Animation derived from the target is applied to particles at the corresponding frames of each particle's existence.
- **Event Duration**—Animation derived from the target is applied to particles is applied to each particle starting when it first enters the event.

**Animated Shape**—Turn on to allow particles to target the surface of an object whose form is animated by scaling, by morphing, or with modifiers. This requires more computation, because the destination must be updated at every integration step.
Follow Target Animation—Turn on to allow particles to follow a moving target; that is, a target whose location is animated. This requires more computation, because the destination must be updated at every integration step.

Point—Lets you specify where on its target a particle should land.
- Random—Each particle targets a random point on the target.
- Closest Surface—Each particle targets the nearest point of the target’s surface.
- By Script Vector—The target point or points are defined using a Script operator that defines values in the particleVector channel. The Script operator can be anywhere upstream of the Find Target test.

Note: When using By Script Vector to target absolute positions, such as vertex locations, be sure to set Target to Icon. If you set it to Mesh, the positions specified by the script will be relative to the position of the mesh object. This latter option is useful for placing scripted targets on the surface of a moving object.

Object—With multiple mesh targets, lets you specify how the software should choose among them. Available only when targeting more than one object.
- Random—For each particle, the software chooses a target object at random.
- Closest Pivot—For each particle, the software chooses as its target the object whose pivot is nearest to the particle.
- Closest Surface—For each particle, the software chooses as its target the object whose surface is nearest to the particle.
- Least Deviation—For each particle, the software chooses as its target the object that requires the least change in its current direction (or restearing) to reach.

By Script Integer—For each particle, the choice of a targeted object is defined by a script operator that sets an index. This index corresponds to a target-object entry position in the target list. See Script Operator Example (page 2–224).

Lock On Target Object—When on, the software calculates each particle’s target object once: when the particle enters the event. Thereafter, the particle is “locked on” to its target object. When off, the software can continually recalculate the target object for each particle. Available only when multiple target objects are designated.

For example, if you set particles to target the closest surface, due to the target animation and particle movement, the definition of the closest surface is constantly changing. Thus the particle may change the target object due to the circumstances.

Note: Each time Find Target sets a target object, it “locks on” to a specific point on that object. This point can change only if the target object changes. Thus, with a single target object, the target point always remains constant relative to the target object. That is, if the target object or its surface is animated, and Follow Target Animation or Animated Shape is on, the absolute coordinates of the target point may change.

Note: When Lock On Target Object is off, more calculation is required because the system might have to recalculate each particle’s optimal target point in each frame.

Docking Direction group

Docking type—Lets you specify from which direction particles should approach targets.
- None Specified—No docking constraints. Particles reach their targets in the most efficient way, based on their assigned parameters and their current attributes.
- Along Icon Arrow—The final direction is the same as the Find Target icon arrow.
  Note: When using this option, arrows appear on the Find Target icon to indicate the direction particles will use for docking. You can change the docking direction by reorienting the icon. This applies even when using mesh objects as targets.

- Icon Spherical—The final direction points toward the center of the operator icon.
  Note: When using this option, arrows appear on the Find Target icon to indicate the directions particles will use for docking. You can change the docking directions by reorienting the icon. This applies even when using mesh objects as targets.

- Icon Cylindrical—The final direction points toward the icon arrow as a line, thus forming a cylindrical field with the arrow as the cylinder’s main axis.
  Note: When using this option, arrows appear on the Find Target icon to indicate the directions particles will use for docking. You can change the docking directions by reorienting the icon. This applies even when using mesh objects as targets.

- Surface Normals—Each particle reaches its target point from a direction perpendicular to the surface at that point.
  Note: When using this option, arrows appear on the Find Target icon to indicate that particles will use surface normals for docking; the actual directions they will use depends on the target surface. This applies even when using mesh objects as targets.

Distance—The distance from the target at which particles begin docking behavior. This includes the docking direction, and, when using Control By Time, the docking speed.

Icon Size—Set the size of the Find Target icon. This affects particle behavior when using the icon as the target.

Color Coordinated—When on, the Find Target icon uses the color of the event containing the test as defined by its local Display operator, if one exists. This applies even if the Display operator is turned off. When off, the Find Target icon uses the default Test Gizmos color as defined in Customize User Interface > Colors > Particle Flow. Default=on.

Turn on Color Coordinated to make it easier to spot the Find Target icon, because the particles in the event use the same color as the icon.

Uniqueness group
The Uniqueness setting enables randomization of the Random options and the Variation options.

Seed—Specifies a randomization value.

New—Calculates a new seed using a randomization formula.

Script Operator Example
Note: See this topic in the online User Reference to view the script operator sample MAXScript code.

Go To Rotation Test

Particle View (page 2–125) > Click Go To Rotation in an event or add Go To Rotation to the particle system and then select it.

The Go To Rotation test enables a smooth transition in the rotational component of a particle, so that the particle can gradually rotate to a specific orientation over a specific period. An example of its usage would be with falling leaves, which spin chaotically as they fall, but land on a flat side rather than an edge. The test aspect lets you direct the particle to a new event when the transition period ends.
To set a target orientation, place the Go To Rotation test before an orientation-type operator (Rotation (page 2–153) or a Script operator (page 2–208) if it defines the rotation channel) in the same event. In this situation, the Go To Rotation test can grab the particle rotational component before the orientation-type operator overwrites it. The Go To Rotation operator modifies the particle orientation and spinning in the post-evaluation cycle. For an example, see the procedure below.

**Warning:** The Go To Rotation test is not compatible with the Spin, Shape Facing, and Shape Mark operators. Do not use any of these operators in the same event with a Go To Rotation test.

**Note:** You can define the transition period only in terms of time. You cannot set the test to come to a specific rotation by the time of another test, such as a collision test. Also, limited control is provided over the axis of spinning when a particle comes to the final rotation.

**Procedure**

**Example: To make falling particles land smoothly, face up:**

This procedure assumes a basic knowledge of Particle Flow usage.

1. In the Perspective viewport, add a Particle Flow system and raise its icon about 80 units on the Z axis.
2. In Event 01, make the following changes:
   - Birth > Amount=50
   - Speed=100
   - Shape=Cube (or use Shape Instance with a custom object, such as a coin-shaped cylinder)
   - Display > Type=Geometry

   This reduces the number of particles and slows them down, making it easier to see what’s going on.

3. Add a Spin operator (page 2–154) to Event 01, and set both Spin Rate and Variation to 150.

   This gives the particles random spinning behavior as they fall.

4. Add an Age test to the end of Event 01, and set Test Value=15.

   This allows each particle to fall and tumble for 15 frames before Go To Rotation takes effect.

5. From the Depot, drag a Go To Rotation test to an empty area in Event Display. Set Duration=15 and keep all other default settings.

6. Insert a Rotation operator immediately after the Go To Rotation test. Choose Random Horizontal as the orientation matrix. Keep the other default settings.

   The Go To Rotation test will use this as the final orientation for the particles.

7. Use a Speed event to create a third event. Set Speed=0.0.

   This stops the particles at the end of the animation.

8. In both new events, set Display > Type=Geometry.

9. Wire the Age Test in Event 01 to Event 02, and then wire the Go To Rotation test in Event 02 to Event 03.

10. Play the animation.

    The particles tumble chaotically as they fall for about 30 frames, and then come to a smooth stop, facing up.
Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

Test True When group

Transition Period Ends—When on, the particles test True at the end of the specified transition period, and become eligible for redirection to the next event. When off, particles will not go to the next event, even if wired. Turn off to disable the test aspect of Go To Rotation. Default=on.

Transition By group

Determines how the software applies the specified timing, defined by the Time and Variation values. Default=Event Duration.

The possible options are:

- **Absolute Time**—Time refers to the overall time of the system. Each particle will reach its target orientation at the frame number specified by Time.

- **Particle Age**—Time refers to the time elapsed since the birth of the particle. Each particle will reach its target orientation when its age reaches the value specified by Time.

- **Event Duration**—Time refers to the time elapsed since the particle entered the current event. Each particle will reach its target orientation when it has been in the current for the number of frames specified by Time.

- **Duration**—The number of frames particles should take to reach the target orientation. Default=30.

- **Variation**—The number of frames by which Duration can vary randomly. Default=0.

To obtain the actual time to the target orientation for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Duration value. For example, if Duration=60 and Variation=20, then the time to target orientation for each particle would be between 40 and 80 frames.

Target Rotation group

When you use an orientation-type operator with Go To Rotation, this setting lets you determine whether the test sets the target orientation on a one-time or ongoing basis. Default=Constant.

- **Constant**—Defines that the orientation-type operator sets a constant orientation for a particle.

For example, when using a Rotation operator set to an orientation matrix other than Speed Space Follow, the Go To Rotation operator would acquire the target orientation only once, and then use it as its goal.
**Changing**—Defines that the orientation-type operator sets a changing rotation for a particle. At each frame the desirable final rotation may be different.

For example, if you use the test with a Rotation operator set to Speed Space Follow, the test will adjust the particle rotation constantly to aim at the changing final rotation.

**Target Rotation Spin group**

Defines the angular velocity for each particle when it reaches the target orientation.

**Match Initial Spin**—Sets the angular velocity at the end of the transition period to the same as the angular velocity when particle enters the event.

*Note:* The axis of rotation might still be different, because it is calculated on the fly to let the particle come to the target orientation.

**Spin Rate**—Defines each particle’s angular velocity, in degrees per second, when it reaches the target orientation. Available only when Match Initial Spin is off. Default=0.0.

For a smooth transition to the target orientation, set to 0.0.

**Variation**—Defines a random variation in the Spin Rate value when a particle reaches the target orientation. Default=0.0.

To obtain the final angular velocity for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Spin Rate value. For example, if Spin Rate=6.0 and Variation=1.0, then the final angular velocity for each particle would be between 5.0 and 7.0 degrees per second.

**Ease In %**—Defines a curve in achieving the final spin rate. Default=0.0

When set to 0.0, the test produces a linear interpolation between the initial and final spin rate, and when set to 100.0, the final spin rate is achieved earlier. For the smoothest approach to the target orientation, set Spin Rate and Variation to 0.0, and Ease In to 100.0.

**Transition End group**

**Stop Spinning**—When on, halts particle rotation when it reaches the target orientation. Default=on.

Even with Spin Rate spinner set to 0.0, we recommend that you keep this check box on to avoid slow spinning at the end, due to computational averaging and marginal errors.

**Uniqueness group**

The Uniqueness setting enables randomization of the Variation options.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

### Scale Test

*Particle View (page 2–125) > Click Scale Test in an event or add Scale Test to the particle system and then select it.*

Scale Test lets the particle system check particle scaling, or particle size before or after scaling, and branch accordingly. The test provides a variety of axis options for measuring scale or size.

You can use this test to cause a change in behavior based on size. For example, a bubble could grow to a certain size, and then pop. Or an object could shrink in size until it falls under the influence of a force, like wind.
Chapter 11: Space Warps and Particle Systems

Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Type**—Choose the type of measurement to test. You can test actual scaling, or the size before or after scaling. Default=Scale.

For example, if the X-axis size of a particle’s bounding box starts out at 10 system units, and you then use the Scale operator to scale it by 150% on the X axis, the pre-scale size is 10, and the post-scale size is 15. And, of course, the scale is 150.

Note: The software measures particle size based on each particle’s bounding-box dimensions in the particle’s local coordinate space. With the low-polygon Shape options Tetra and Sphere, the result of this measurement might not be the same as the Shape operator’s Size value.

- **PreScale Size**—Tests the size before scaling.
- **PostScale Size**—Tests the size after scaling.
- **Scale**—Tests the scaling percentage.

**Axis**—Choose the axis to measure. Default=Average.

- **Average**—Obtains an average measurement by adding the sizes on all three axes and then dividing by three.
- **Minimum**—Uses the smallest dimension.
- **Median**—Uses the middle dimension in order of size. For example, if the particle dimensions are X=5, Y=6, Z=12, then the number compared to Test Value would be 6.
- **Maximum**—Uses the largest dimension.
- **X/Y/Z**—Uses the specified dimension.

**Test True If Particle Value**—Lets you specify whether the test passes particles on to the next event if the speed test succeeds or fails. Available for all tests except True When Accelerates/Decelerates. Default=Is Greater Than Test Value.

By default, Scale Test returns True if the value tested for exceeds the Test Value quantity, but you can alternatively choose Is Less Than Test Value. For example, if you set Type to Scale and set Test Value=150 and Variation=0, and choose Is Less Than Test Value, a particle will move to the next event only when its scaling factor is less than 150%.

**Size group**

These settings are available when Type is set to PreScale Size or PostScale Size.

- **Test Value**—The specific size to test for. Default=10.0.
- **Variation**—The amount by which the value tested for can vary randomly. Default=0.0.

To obtain the actual test value for each particle, the system multiplies the Variation value by a random
number between -1.0 and 1.0, and then adds the result to the Test Value setting. For example, if Test Value=10 and Variation=5, then the tested value for each particle would be between 5 and 15.

**Scale group**

These settings are available when Type is set to Scale.

**Test Value**—The specific scaling factor to test for. Default=100%.

**Variation**—The amount by which the value tested for can vary randomly. Default=0.0%.

To obtain the actual test value for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Test Value setting. For example, if Test Value=100% and Variation=10%, then the tested value for each particle would be between 90% and 110%.

**Test Value Offset Keying group**

**Sync By**—Choose the time frame to use when animating Test Value and Variation:

- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
- **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.

**Uniqueness group**

The Uniqueness setting enables randomization of the test value variation. Available only when either Variation value exceeds 0.0.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

---

**Script Test**

Script Test lets you test particle conditions using a MAXScript script. The script can use any program functionality available to MAXScript.

The default test script tests for the presence of all particles within a spherical volume of radius 20.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Edit Script**—Click this button to open the current script in a MAXScript Editor window.

For detailed information about the MAXScript utility, open the MAXScript Reference, available from Help menu > MAXScript Reference.

**Uniqueness group**

The Uniqueness setting provides a randomization seed that the script can use or ignore.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.
Chapter 11: Space Warps and Particle Systems

Send Out Test

Particle View (page 2–125) > Click Send Out in an event or add Send Out to the particle system and then select it.

The Send Out test simply sends all particles to the next event, or, conversely, keeps all particles in the current event. Use Send Out when you simply want to send particles to another event without any conditions.

Tip: You can temporarily convert any test to Send Out. To specify that a test should send all particles out without any conditions, click the left side of its icon in Particle view; the icon changes to a green light bulb to indicate that all particles automatically test True. Or, if you click the right side of the icon, it changes to a red light bulb, indicating that all particles test False and thus will stay in the current event. To revert to the test’s original function, click its icon again.

Interface

Test True For—Lets you specify whether the test passes all particles on to the next event or keeps them in the current event. Default=All Particles.

- All Particles—All particles are passed on to the next event.
- No Particles—All particles are retained in the current event.

Spawn Test

Particle View (page 2–125) > Click Spawn in an event or add Spawn to the particle system and then select it.

Spawn creates new particles from existing ones. Each spawned particle is born at the same location as its parent, and has the same orientation and shape. Spawn can give the spawned particles a different speed and scaling factor. If you wire the Spawn test to another event, spawned particles are sent to that event, where you can specify different properties for the new particles.

Spawn is a test only in that it sends the spawned particles to another event (if wired); it doesn’t actually test any properties. All particles that encounter Spawn are immediately affected by it. Thus, if you want particles to spawn based on the results of a test, use a different test that branches to an event containing the Spawn. In such a case, you might want to then send the spawned particles to yet another event, or the particles will continually respawn. Alternatively, to spawn particles after a collision, use Collision Spawn Test (page 2–215).

See also

Collision Spawn Test (page 2–215)
Interface

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

In the context of Spawn, a parent is the original particle from which new particles are spawned.

Spawn Rate And Amount group

Use these settings to specify how often particles are to spawn, the measurement system to use, and other values related to how many particles are spawned.

Once—Particles spawn one time only. For each existing particle, one new one is born.

Delete Parent—When on, deletes each original particle from which a new one is spawned. Available only with the Once option.

Per Second—Lets you specify a number of particles to spawn every second. For example, if you use the default Rate setting of 10.0, at 30 fps a new particle is born every three frames.

Rate—The number of particles to spawn per second. Available only with the Per Second option.

By Travel Distance—Lets you spawn new particles at regular intervals over the path of a moving parent particle.

Step Size—The system spawns a new particle every time the parent moves this distance, in system units.

Spawnable—The percentage of particles in the current event that will spawn new particles. This is determined once for each particle, when it enters the event. However, the parameter is animatable. Default=100.0.

For values other than 100.0, Spawnable uses a randomized selection process, which is affected by the Uniqueness Seed value. For example, with five parent particles, Offspring#=1, and Spawnable=80.0, you might get any number of spawned particles between two and five. The average per spawning would be four, however.

Offspring#—The number of new particles the system creates from each parent particle for each spawning event. Default=1.

Variation—The amount by which the Offspring# value can vary randomly. Default=0.0.

To obtain the actual test value for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then applies the result as a percentage of the Offspring# setting.
For example, if Offspring #$=20$ and Variation$=10$, then the actual number of offspring for each particle would be between 18 and 22.

**Sync By**—Choose the time frame to use when animating Rate, Step Size, Offspring $\#$, and Variation:

- **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.
- **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.
- **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.

**Restart Particle Age**—When on, sets the age of each newly spawned particle at 0. When off, each spawned particle inherits its parent’s age. Default=on.

**Speed group**

Let’s you specify the speed of spawned particles in absolute terms or relative to the parent’s speed, with optional random variation. The direction of a spawned particle is always in relation to that of its parent, but you can set a Divergence so they eventually spread out. Default=Inherited.

**In Units**—Choose this to specify the speed of spawned particles in system units per second. Default=100.0.

A positive value inherits the parent’s direction; a negative value reverses it.

**Inherited**—Choose this to specify each spawned particle’s speed as a percentage of its parent’s speed. Default=100.0

A positive value inherits the parent’s direction; a negative value reverses it.

**Variation**—The amount by which a spawned particle’s speed can vary randomly. Default=0.0.

To obtain the actual speed for each spawned particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the particle’s speed as specified or inherited. For example, if a particle’s speed is 100 units/second and Variation=20, then the tested value for each particle would be between 80 and 120 units/second.

**Divergence**—When on, spreads out the stream of spawned particles. Use the numeric setting to define the extent of the divergence in degrees. Range=0 to 180. Default=0.

**Size group**

**Scale Factor**—The amount of uniform scaling to apply to each spawned particle, as a percentage of its parent’s size. Default=100.0.

**Variation**—The amount by which a spawned particle’s scale can vary randomly. Default=0.0.

To obtain the actual scaling for each spawned particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Scale Factor value. For example, if Scale Factor=100 and Variation=20, then each spawned particle would be between 80 and 120 percent of its parent’s size.

**Uniqueness group**

The Uniqueness setting enables randomization of the Spawnable result, when less than 100.0, as well as of the Variation values.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.
Speed Test

*Particle View (page 2–125)* > Click Speed Test in an event or add Speed Test to the particle system and then select it.

Speed Test lets the particle system check particle speed, acceleration, or the rate of circular travel, and branch accordingly. The test provides a number of variants that let you test speed or acceleration on specific axes, or simply whether the particle is accelerating or decelerating.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

The first interface element is a drop-down list that lets you choose the type of measurement to test:

- **Velocity Magnitude**—Tests the particle velocity, in system units per second, without consideration of direction. This is the default test type.
- **Velocity X/Y/Z**—Tests the particle velocity on the specified axis, in system units per second per second, using the world coordinate system.
- **Acceleration Magnitude**—Tests the particle acceleration (change in velocity), in system units per second per second, without respect to direction.
- **Acceleration X/Y/Z**—Tests the particle acceleration (change in velocity) on the specified axis, in system units per second per second, using the world coordinate system.
- **Steering Rate**—Tests the circular component of particle travel in degrees per second, without consideration of rotation or spinning.

An example of this option would be with fireworks: As the particles move upward, their velocity on the world Z axis is positive. When the reach the top of their trajectory and begin to move downward, their velocity on the world Z axis slows to 0, and then becomes negative. If you choose Velocity Z and Is Less Than Test Value, and set Test Value to 0.0, you can send particles to another event at the moment they begin to move downward.

- **Acceleration Magnitude**—Tests the particle acceleration (change in velocity), in system units per second per second, without respect to direction.
- **Acceleration X/Y/Z**—Tests the particle acceleration (change in velocity) on the specified axis, in system units per second per second, using the world coordinate system.
- **Steering Rate**—Tests the circular component of particle travel in degrees per second, without consideration of rotation or spinning.

For example, if a particle travels along a parabolic path, its motion has both linear and circular components. The circular component is greatest at the top of the parabola. If a particle travels in a full circle in one second, the rate is 360; if it travels in a half circle, the rate is 180.

Potential usage: When a particle is forced to turn too sharply, it might explode or change its type of movement. For example, missiles chase a jet fighter, which maneuvers to elude the missiles. The missiles are forced to change their course rapidly, but the missile construction cannot stand the fast change in steering, so the missiles blow up or disintegrate.

**Tip:** You can test steering rate by setting the particle speed with *Speed By Icon (page 2–162)*, and linking the Speed By Icon operator icon to a circular path.

- **True When Accelerates**—Returns a True value when the particle velocity is increasing in value.
• **True When Decelerates**—Returns a True value when the particle velocity is decreasing in value.

**Test True if Particle Value**—Lets you specify whether the test passes particles on to the next event if the speed test succeeds or fails. Available for all tests except True When Accelerates/Decelerates. Default=Is Greater Than Test Value.

By default, Speed Test returns True if the value tested for exceeds the Test Value quantity, but you can choose Is Less Than Test Value as well. For example, if you use the Velocity Magnitude test type and set Test Value=200 and Variation=0, and choose Is Less Than Test Value, then particles will move to the next event only when they travel faster than 200 units per second. Any particles traveling 200 units per second or slower stay in the current event unless they later exceed that speed or another test returns True.

**Test Value**—The specific speed or acceleration to test for. The unit of measurement depends on the type of test; see above. Default=300.0.

**Variation**—The amount by which value tested for can vary randomly. Default=0.0.

To obtain the actual test value for each particle, the system multiplies the Variation value by a random number between -1.0 and 1.0, and then adds the result to the Test Value setting. For example, if Test Value=300 and Variation=10, then tested value for each particle would be between 290 and 310.

**Sync By**—Choose the time frame to use when animating Test Value and Variation. For further information, see *Animation Offset Keying group* (page 2–158).

• **Absolute Time**—Any keys set for parameters are applied at the actual frames for which they’re set.

• **Particle Age**—Any keys set for parameters are applied at the corresponding frames of each particle’s existence.

• **Event Duration**—Any keys set for parameters are applied to each particle starting when it first enters the event.

**Uniqueness group**

The Uniqueness setting enables randomization of the test value variation.

**Seed**—Specifies a randomization value.

**New**—Calculates a new seed using a randomization formula.

### Split Amount Test

![Particle View (page 2–125) > Click Split Amount in an event or add Split Amount to the particle system and then select it.](image)

The Split Amount test lets you send a specific number of particles to the next event, keeping all remaining particles in the current event. You can split the particle stream by a specific number or percentage, or by every Nth particle. With a specific number of particles, the splitting takes place once per event, but you can animate the percentage and “every Nth” values to vary the amount of split-off particles over time.
The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Test True For group**

Lets you choose how to split the particle stream. Default=Fraction Of Particles, 50%.

- **Fraction Of Particles**—Split the particle stream on a percentage basis, specified with the Ratio value. With Ratio greater than 0.0, whether a particular particle is split off depends on a randomization factor; change this with the Uniqueness Seed value.

  - **Ratio**—Specify the percentage of particles that will test True. Animatable. Default=50.0.

    Available only with the Fraction Of Particles option.

  - **Every Nth Particle**—Splits off a regular sample of particles.

    - **N**—Specify how often to split off a particle. Animatable. Default=3.

      For example, enter 8 to split off every eighth particle.

      Available only with the Every Nth Particle option.

- **First N Particles**—Splits off the number of particles specified as the N value (below), starting with the first particle to enter the event, and retains the rest.

- **Particles After N First**—Splits off all particles starting with the first one after N particles, as specified with the N parameter (below). All particles starting with the first to enter the event up to N are retained in the event.

  - **N**—Specify the number of particles to split off, with First N Particles, or to retain in the event, with Particles After N First.

    Available only with the First N Particles or the Particles After N First option.

- **Per Emission Source**—When on, the software applies the N value for the options First N Particles and Particles After N First separately for each emission source.

  Use this option with multiple Particle Flow sources converging into a single Split Amount test.

**Uniqueness group**

The Uniqueness setting enables randomization of particle retention with the Fraction Of Particles option.

- **Seed**— Specifies a randomization value.

- **New**—Calculates a new seed using a randomization formula.

**Split Selected Test**

The Split Selected test lets you split the particle stream based on particles’ selection status. For information about selecting particles, see *Selection rollout* (page 2–138).
Chapter 11: Space Warps and Particle Systems

Note: This test considers only particles selected at the Particle sub-object level. To use all particles in an event at a specific frame, go to that frame, go to the Event sub-object level, and highlight the event. Then go to the Particle sub-object level, and on the Selection rollout, click Get From Event Level.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Test True If Particle group**

Lets you choose how to split the particle stream. Default=Is Selected.

- **Is Selected**—All selected particles are eligible for redirection to another event.
- **Is Not Selected**—All non-selected particles are eligible for redirection to another event.

**Split Source Test**

The Split Source test lets you split the particle stream based on particles' origin. You can specify that particles from one or more specific Particle Flow sources should or should not be eligible for redirection to the next event.

**Interface**

The user interface appears in the parameters panel, on the right side of the Particle View dialog.

**Test True If Particle group**

Lets you choose how to split the particle stream. Default=Is From Selected Source.

- **Is From Selected Source**—All particles from sources highlighted in the Selected Emission Sources list are eligible for redirection to another event.
- **Is Not From Selected Source**—All particles from sources not highlighted in the Selected Emission Sources list are eligible for redirection to another event.

**Selected Emission Sources**—Lists all emission sources in the system. Highlight the sources to be considered by the test.
Non-Event-Driven Particle Systems

Create panel > Geometry > Particle Systems
Create menu > Particles

Non-event-driven particle systems provide relatively simple, straightforward methods for generating particle sub-objects over time for the purpose of simulating snow, rain, dust, and so on. You use particle systems primarily in animations.

3ds Max provides six built-in, non-event-driven particle systems:

- Spray Particle System (page 2–244)
- Snow Particle System (page 2–246)
- Super Spray Particle System (page 2–249)
- Blizzard Particle System (page 2–251)
- PArray Particle System (page 2–256)
- PCloud Particle System (page 2–253)

Note: You can take advantage of the AutoGrid feature to orient and position new particle systems with respect to existing objects. For details, see AutoGrid (page 2–7).

Interface

Snowstorm created as a particle system

This topic describes only the general properties of particle systems. Other plug-in particle systems might be available in your configuration.

The built-in particle systems share these controls:

**Emitter**—Specifies where in the scene the particles are generated. The emitter is the particle system’s main sub-object. It doesn’t render. Particles appear on the surface of the emitter and fall (or drift, drop, flurry, spray) from the emitter in a particular direction.

**Timing**—The timing parameters control the dynamics of particles in the system. They specify how quickly particles appear, how quickly they disappear, whether the emission rate is constant, and so on.

**Particle-specific parameters**—These parameters are specific to the kind of particle system. Examples are particle size and speed.

**Rendering properties**—These parameters are also specific to the kind of particle system. There are options for displaying particles in viewports and rendering them in scenes and animations. Particles do not necessarily appear the same in renderings as they do in viewports.

You can modify and animate particle system parameters. You can also affect particle system behavior with space warps (page 2–55). In addition, you can deform particle systems with the Mesher compound object (page 1–374).
Note: Particles can participate in dynamics simulations.

* Particle Flow (page 2–109)

### Using Particle Systems

You create particle systems when you want to model an object or effect that can best be described as a large collection of similar objects behaving in a similar fashion. Obvious examples of such effects include rain and snow, but other equally valid examples include water, smoke, ants, and even crowds of people.

On the Create panel, click Spray, Snow, Super Spray, Blizzard, PArray, or PCloud to create a particle system. Spray and Snow exist primarily for compatibility with earlier releases of 3ds Max, and are superseded by Super Spray and Blizzard.

To create a particle system, first choose Create menu > Particles > Spray or Snow.

These are the basic steps for creating a particle system:

1. Create a particle emitter. All particle systems require an emitter. Some particle systems use the particle system icon as the emitter while others use an object you select from the scene as the emitter.

2. Determine the number of particles. You set parameters such as birth rate and life span to control how many particles can exist at any given time.

3. Set particle shape and size. You can select from many standard particle types (including metaballs) or you can select an object to be emitted as a particle.

4. Set initial particle motion. You can set the speed, direction, rotation, and randomness of particles as they leave the emitter. Particles can also be affected by animation of the emitter.

5. Modify particle motion. You can further modify the motion of particles after they leave the emitter by binding the particle system to a space warp in the Forces group, such as Path Follow, or make them bounce off a deflector in the Deflectors space warp group, such as UDeflector.

**Important:** When you use forces and deflectors together, always bind the forces before the deflectors.

**Tip:** If the particles don’t follow the emitter after it’s moved, then change any Path Follow parameter (page 2–71). The motion will be applied to the particles.

### Rain and Snow

Create rain and snow using Super Spray (page 2–249) and Blizzard (page 2–251). These particle systems are optimized for droplet (Super Spray) and tumbling flake (Blizzard) effects. Add space warps such as Wind (page 2–75) to create spring rains or winter storms.

### Bubbles

Create bubbles by using the Bubble Motion options of Super Spray (page 2–249). If you require good rendering speed, consider using constant or tetra particles. If you require bubble detail, consider using opacity-mapped facing particles, instanced spheres, or metaparticles.

### Flowing Water

You generate flowing liquid effects by setting Super Spray (page 2–249) to generate closely packed
Creating a Particle Emitter

After you choose a particle system type to add, you create the particle system icon in the scene. The icon serves different purposes depending on the type of particle system.

**As an emitter:** The icon defines the starting location and direction of the particles. Spray, Snow, Super Spray, Blizzard, and Particle Cloud use the icon as the particle emitter.

**As a placeholder:** The icon serves only to hold the parameters for the particle system. The particles are emitted from another selected object. Particle Array and Particle Cloud use the icon as a placeholder.

The following particle effects are described in detail:

**Explosions**

*Particle Array (PArray) (page 2–256)* uses another object as its particle emitter. You can set the particle type to use fragments of the emitter object to simulate the object exploding.

**Volume Effects**

*Particle Cloud (PCloud) (page 2–253)* constrains its particles within a specified volume. You can use Particle Cloud to generate bubbles in a glass of soda, or bees buzzing inside a jar.

**Crowds**

*Super Spray (page 2–249), Blizzard (page 2–251), Particle Array (page 2–256), and Particle Cloud (page 2–253)* can use instanced geometry as their particle type. You can create a stream of ants, a flock of birds, or a cloud of dandelion seeds using instanced geometry particles.

You can choose whether Particle Cloud uses its icon or another selected object as the emitter.

**Procedures**

**To create emitter icons:**

- Drag in a viewport to set the size and orientation of the particle emitter icon for Spray, Snow, Super Spray, Blizzard, and Particle Cloud.

Spray, Snow, Blizzard, and Particle Cloud use the icon size as the area of particle emission. Super Spray emits particles from its center regardless of its icon size.

All particle systems align the particle direction with the Z axis of the creation grid.

**To create placeholder icons:**

1. Drag in a viewport to set the size of the placeholder icon for Particle Array and Particle Cloud.

The size and location of the particle system icon has no effect on the particles.

2. After placing the particle system icon, click Pick Object on the Basic Parameters rollout to select the object to use as the particle emitter.

**Using Materials with Particle Array**

The material that appears on the particles comes from one of three places:

- The particle system itself
- The material assigned to the distribution object (PArray only)
- The material assigned to the instanced objects
You make this choice in the Material Mapping and Source group near the bottom of the Particle Type rollout. Choose Icon to use the material assigned to the particle system, choose Picked Emitter to use the material assigned to the distribution object, or choose Instanced Geometry to use the material assigned to the instanced objects. Note that this third option is available only when Instanced Geometry is the current particle type (selected in the Particle Types group at the top of the Particle Type rollout).

Note: SuperSpray and Blizzard don’t have distribution objects. PCloud has a distribution object but you can’t get the material from it. In these cases, a radio button lets you use the material from the instanced geometry. Only PArray lets you get the material from the distribution object.

Important: A particle-system object, like any other object, can carry only a single material at any time. Thus, if you choose either Picked Emitter or Instanced Geometry, an instance of the chosen material is actually copied to the particle system, overwriting the material assigned to the emitter. If you want to restore the emitter material, choose Icon, and then reassign the material from the Material Editor or the Browser.

No matter what choice you make, if the material used is not mapped, then all particles take on the surface properties of the material, regardless of which object is used as the source of the material.

### Achieving Particle Motion Blur

Particle motion blur is actually the result of varying the opacity and the length of particles based on their speed. To accomplish this requires coordination between material assignment and the settings in the particle systems. Follow these instructions:

- Use the Particle MBlur map (page 2–1676) in the material that you assigned to the particles. For best results, assign it as an opacity map.
- Make sure that the particle system, PArray, PCloud, and Super Spray, or Spray, supports the Particle MBlur map.
- Choose Rotation and Collision rollout > Spin Axis Controls group > Direction of Travel/Mblur option.
- In this same group, set the Stretch spinner greater than 0 to stretch the particles as a percent of their length based on the particle Speed setting.
- Use the correct type of particle. MBlur works on all particle types except Constant and Facing.

Note: Instanced objects with multi/sub-object materials cannot be image motion blurred.

### Using Mapped Materials with Particle Systems

Mapped materials affect particles differently, depending on the source of the material.
When you choose Icon, the mapping coordinates of the material are applied across the V (vertical) axis, from V=0 (the bottom edge of the map) to V=1 (the top edge of the map). The bottom edge of the map is applied at the birth of the particle, and the top edge at either the death of the particle (if Time is on) or the distance of the particle at its death (if Distance is on).

The Time spinner specifies the number of frames from birth that it takes to complete one mapping of a particle. Thus, if set to 15, the particle uses the bottom edge of the map at its birth, and moves through to the top edge of the map at frame 15.

The Distance spinner specifies the distance, in units, from birth that it takes to complete one mapping of a particle. Thus, if set to 50, as the particle moves along the normal vector, it displays the bottom edge of the map at birth, and the top edge at 50 units along the normal vector.

The one exception to this is when you use the Tetra particle type. In this case, each particle is always constantly mapped with V=0 at the head and V=1 at the tail.

When you choose Picked Emitter, the particles take on the color of the object at the point at which they’re created. If the mapped surface is yellow where the particle emerges, then the particle is yellow.

Again, Tetra particles are an exception and the distribution-object material is mapped from head to tail.

Fragment particles use the same technique, with additional options when the Thickness setting is greater than 0.

When Thickness is 0, all faces in the fragment are mapped the same as the portion of the object surface from which they’re derived.

When Thickness is greater than 0, the outer faces of the fragment copy the surface of the distribution object, and are assigned the material ID specified in the Outside ID spinner in the Particle Type rollout > Fragment Materials group. The thickness edges use the Edge ID number, and the inner faces use Backside ID. Thus, by assigning a multi/sub-object material to the object-based emitter, you can specify a different material for the outer fragment surfaces, the edges, and the inner surfaces. Note that the Outside ID spinner defaults to a value of 0, which means "use whatever material is currently assigned." Change this to a specific sub-material number to assign a sub-material to the outside edges of the fragments.
Using Multi/Sub-Object Materials with Particle Systems

If the assigned material is a Multi/Sub-Object material, particles are affected in the following ways, depending on the source of the material:

- **Icon:** In most cases, each particle, at its birth, is assigned a different sub-material, cycling through each available sub-material. For example, if there are only three sub-materials, the first particle receives sub-material #1, the second #2, the third #3, the fourth #1, and so on. The exceptions to this are as follows:
  - MetaParticles use only the first sub-material.
  - Object fragments are born at once, so all of them use only the first sub-material.
  - **Picked Emitter:** When used with object fragments as particles, each particle uses the three ID numbers in the Fragment Materials group. If this source is used with the other particle types, the particles are assigned sub-materials in the same way as when Icon is chosen.
  - **Instanced Geometry:** When used with Instanced Geometry particles, each particle is assigned a sub-material in exactly the same way as the source object, so each particle looks just like the source object. When used with other particle types, the particles are assigned sub-materials in the same way as when Icon is chosen.

Note: Instanced objects with Multi/Sub-Object materials cannot be image motion blurred.

Using Spawned Particles

The examples in this topic start you out with a very simple spawning using the Super Spray particle system.

**Example: Setting up the particle system:**

1. In the Perspective viewport, create a pyramid that’s 5 units in all dimensions.
2. Create a cylinder with a radius and height of 3, and 6 sides.
3. In the center of the Perspective viewport, create a Super Spray emitter.
4. Set Speed in the Particle Motion group (Particle Generation rollout) to 3.0.
5. On the Particle Type rollout, choose Instanced Geometry, then in the Instancing Parameters group click Pick Object, and select the pyramid.
6. In the Viewport Display group of the Basic Parameters rollout, choose Mesh and set the Percentage of Particles to 100.
7. On the Particle Generation rollout, choose Use Rate, and set the spinner to 1.
8. Set Emit Start and Emit Stop to 0, set Display Until to 100, set Life to 10, and leave Variation at 0.
9. Under Particle Size, set Grow For and Fade For to 0.
10. Drag the time slider between frames 0 and 15. A single pyramid particle emerges from the emitter, moves up, and then dies and disappears at frame 10.
Using Interparticle Collision

Example: Adding spawning effects:
1. On the Particle Spawn rollout, choose Spawn on Death.
2. Leave Spawns spinner at 1, and set the Multiplier to 2.
3. Set the Direction Chaos spinner to 50.
4. Drag the time slider slowly over frames 8 to 25 (approximately).
   At frame 10, two pyramids appear at the death of the original particle (because of the Multiplier setting), and move off in different directions (because of the Direction Chaos setting). All particles die after frame 20 because only one generation of spawned particles is specified.
5. Set Spawns to 4, and the Multiplier to 4.
6. Drag the time slider over frames 8 to 50.
   With each spawned generation the particles increase exponentially.

Example: To mutate the objects:
1. In the Object Mutation Queue group, click Pick Object, and then select the cylinder. The name of the cylinder appears in the list window.
2. Click Pick Object and select the pyramid. Then click Pick Object again, and select the cylinder. Your list now reads: Cylinder01, Pyramid01, Cylinder01.
3. Drag the time slider over frames 0 to 50.
   The pyramid appears over frames 0 to 10, then changes to four cylinders at frame 11, then 16 pyramids at the next spawning, and so on.

Using Interparticle Collision

Particles colliding and then rebounding

You can set up particles to detect collisions with each other. This can be useful when the particles are meant to model solid objects such as marbles.

Procedure

Example: To create particles that collide with each other:
1. Create a Super Spray particle emitter, and place a Deflector space warp (page 2–90) a short distance from it with the surface of the deflector perpendicular to the stream of the particles. Bind the deflector to the Super Spray.
2. Set the Super Spray values as follows:
   • Off Axis: 1, Spread: 1, Off Plane: 180, Spread: 180
   • Mesh: chosen, Percent of Particles: 100
   • Particle Quantity: Use Rate chosen and set to: 1
   • Speed: 3, Variation: 100%
   • Emit Start: 0, Emit Stop: 5, Display Until: 100, Life: 100
   • Size: 4.0, Grow For: 0, Fade For: 0
   • Particle Type: Sphere
3. Drag the time slider so you can see the particle spheres bounce off the deflector. Note that the rebounding particles move through each other.

4. On the Rotation & Collision rollout, turn on Enable in the Interparticle Collisions group. View the animation again. This time, the particles bounce off each other.

Tip: InterParticle Collisions, Deflector Binding, and Bubble Noise do not get along well together. Particles may leak through the deflector when these three are used together. Instead of bubble motion use animated mapping. Use facing particles with an animated map of a bubble, where the bubble is smaller than the map size. The bubble is animated moving around the map. This simulates bubble motion at the map level.

Spray Particle System

Create panel > Geometry button > Choose Particle Systems from the drop-down list > Object Type rollout > Spray

Create menu > Particles > Spray

Spray simulates water drops such as rain, a fountain, the spray from a garden hose, and so on.

Tip: To animate particles following a path through space, use the Path Follow space warp (page 2–71).

Procedure

To create spray:

1. On the Create panel, make sure the Geometry button is active and Particle Systems is chosen in the object category list, then click Spray.

2. Drag in a viewport to create the Spray emitter; see Creating a Particle Emitter (page 2–239). The emitter’s direction vector points in the negative Z direction of the active construction plane. For example, if you create the emitter in the Top viewport, the particles will move downward in the Front and Left viewports.

Kinds of Spray

Note: SuperSpray (page 2–249) is a more powerful and advanced version of Spray. It provides all the functionality of Spray, plus additional features.

**Particles group**

**Viewport Count**—Maximum number of particles displayed in viewports at any given frame.

**Render Count**—Maximum number of particles that can appear in a single frame when you render it. Works in combination with the particle system’s timing parameters.

- When the number of particles reaches the Render Count value, particle creation is suspended until some particles die.
- When enough particles die, particle creation resumes until Render Count is reached again.

**Drop Size**—Size of a particle in the active units.

**Speed**—Initial velocity of each particle as it leaves the emitter. Particles travel at this speed unless they are affected by a particle system space warp.

**Variation**—Varies the initial speed and direction of particles. The greater the Variation, the stronger and broader the spray.

**Drops, Dots, or Ticks**—Choose how particles are displayed in viewports. The display setting does not affect how particles are rendered. Drops are streaks that appear like raindrops, dots are points, ticks are small plus signs.

**Render group**

**Tetrahedron**—Particles are rendered as long tetrahedrons, with the length you specify in the Drop Size parameter. Tetrahedron is the default setting for rendering. It provides a basic simulation of water drops.

**Facing**—Particles are rendered as square faces whose width and height equals the Drop Size. Facing particles always face the camera (or the user’s perspective). They are provided especially for use with material maps. Use with an appropriate opacity map for bubbles or snowflakes.

**Note:** Facing works correctly only in a perspective or camera view.

**Timing group**

Timing parameters control the "birth and death" rates of emitted particles.

At the bottom of the Timing group is a line that displays the maximum sustainable rate. This value
is based on the Render Count and the lifetime of each particle. To be precise:

maximum sustainable rate = Render Count / Life

Because the number of particles in a frame never exceeds Render Count, if the Birth Rate exceeds the maximum rate, the system will run out of particles, pause until some die off, and then start again, generating particles in bursts or spurts.

Start — Number of the first frame where particles appear.

Life — The lifetime of each particle, in number of frames.

Birth Rate — The number of new particles born per frame.

If this is less than or equal to the maximum sustainable rate, the particle system generates an even flow of particles. If it is greater than the maximum rate, the particle system generates particles in bursts.

You can animate the Birth Rate parameter.

Constant — When on, Birth Rate is unavailable and the birth rate used equals the maximum sustainable rate. When off, Birth Rate is available. Default = on.

Turning Constant off does not mean that the birth rate varies automatically; the birth rate remains constant unless you animate the Birth Rate parameter.

Emitter group

The emitter specifies the area where particles appear in the scene. It has a geometry you can display in viewports, but it isn’t renderable.

The emitter is displayed as a rectangle with a vector pointing out of one side. The vector shows the direction in which the system emits particles.

Width and Length — You implicitly set the initial value of these parameters when you drag in a viewport to create the emitter. You can adjust the values in the rollout.

The space occupied by the particle system at any given time is the result of a combination of its initial parameters (such as size of the emitter, and speed and variation of emission) and any space warps that have been applied.

Hide — Turn on to hide the emitter in viewports. When Hide is off, the emitter is displayed in viewports. The emitter is never rendered. Default = off.

Snow Particle System

Snow simulates falling snow or confetti. The snow system is similar to Spray, but it has additional parameters to generate tumbling snowflakes, and its rendering options are different.

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > Snow

Create menu > Particles > Snow

Snow simulates falling snow or confetti. The snow system is similar to Spray, but it has additional parameters to generate tumbling snowflakes, and its rendering options are different.
Kinds of Snow

Note: Blizzard (page 2–251) is a more powerful and advanced version of Snow. It provides all the functionality of Snow, plus additional features.

Tip: To animate particles following a path through space, use the Path Follow space warp (page 2–71).

Procedure

To create snow:

1. In the Create panel, make sure the Geometry button is active and Particle Systems is selected from the object category drop-down list, then click Snow.

2. Drag in a viewport to create the Snow emitter; see Creating a Particle Emitter (page 2–239).

The emitter’s direction vector points in the negative Z direction of the active construction plane.

Particles group

**Viewport Count**—Maximum number of particles displayed in viewports at any given frame.

Tip: Setting the viewport count less than the render count can improve viewport performance.

**Render Count**—Maximum number of particles that can appear in a single frame when you render it.
Chapter 11: Space Warps and Particle Systems

Works in combination with the particle system’s timing parameters.

- When the number of particles reaches the Render Count value, particle creation is suspended until some particles die.
- When enough particles die, particle creation resumes until Render Count is reached again.

**Flake Size**—Size of a particle in the active units.

**Speed**—Initial velocity of each particle as it leaves the emitter. Particles travel at this speed unless they are affected by a particle system space warp.

**Variation**—Varies the initial speed and direction of particles. The greater the Variation, the broader the area of snowfall.

**Tumble**—Amount of random rotation for snowflake particles. This parameter can range from 0 to 1. At 0, flakes do not rotate; at 1, they rotate the most. The axis of rotation is generated randomly for each particle.

**Tumble Rate**—Speed at which snowflakes rotate. The greater the Tumble Rate, the faster the rotation.

**Flakes, Dots, or Ticks**—Select how particles are displayed in viewports. The display setting does not affect how particles are rendered. Flakes are star-shaped snowflakes, dots are points, ticks are small plus signs.

**Render group**

**Six Point**—Each particle is rendered as a six-pointed star. Each side of the star is a face to which you can assign a material. This is the default setting for rendering.

**Triangle**—Each particle is rendered as a triangle. Only one side of the triangle is a face to which you can assign a material.

**Facing**—Particles are rendered as square faces whose width and height equals the Drop Size.

Facing particles always face the camera (or the user’s perspective). They are provided especially for use with material maps. Use with an appropriate opacity map for bubbles or snowflakes.

Note: Facing works correctly only in a perspective or camera view.

**Timing group**

Timing parameters control the "birth and death" rates of emitted particles.

At the bottom of the Timing group is a line that displays the maximum sustainable rate. This value is based on the Render Count and the lifetime of each particle. To be precise:

maximum sustainable rate = Render Count / Life

Because the number of particles in a frame never exceeds Render Count, if the Birth Rate exceeds the maximum rate, the system will run out of particles, pause until some die off, and then start again, generating bursts or spurts of particles.

**Start**—Number of the first frame where particles appear.

**Life**—The lifetime of a particle, in number of frames.

**Birth Rate**—The number of new particles born per frame.

If this is less than or equal to the maximum sustainable rate, the particle system generates an even flow of particles. If it is greater than the maximum rate, the particle system generates particles in bursts.

You can animate the Birth Rate parameter.

**Constant**—When on, Birth Rate is unavailable and the birth rate used equals the maximum sustainable rate. When off, Birth Rate is available. Default=on.
Turning Constant off does not mean that the birth rate varies automatically; the birth rate remains constant unless you animate the Birth Rate parameter.

Emitter Group

The emitter specifies the area where particles appear in the scene. It has a geometry you can display in viewports, but it isn't renderable.

The emitter is displayed as a rectangle with a vector pointing out of one side. The vector shows the direction in which the system emits particles.

You set emitter parameters in the Emitter group of the particle system's Parameters rollout.

Width and Length—You implicitly set the initial value of these parameters when you drag in a viewport to create the emitter. You can adjust the values in the rollout.

The space occupied by the particle system at any given time is the result of a combination of its initial parameters (size of the emitter, and speed and variation of emission) and any space warps that have been applied.

Hide—Turn on to hide the emitter in viewports. When off, the emitter is displayed in viewports. The emitter is never rendered. Default=off.

Super Spray Particle System

Super Spray emits a controlled spray of particles. This particle system is like the simple Spray particle system with the added power provided by all the newer particle systems.

Tip: To animate particles following a path through space, use the Path Follow space warp (page 2–71).

Procedure

To create a super spray particle system:

1. On the Create panel, make sure the Geometry button is active and Particle Systems is chosen in the object category list, then click Super Spray.

2. Drag in any viewport to create the Super Spray emitter icon; see Creating a Particle Emitter (page 2–239).

The icon appears as an intersecting plane and circle with an arrow. The initial direction of the

Super Spray viewport icon (emitter)

Particles emerging from a super spray system
spray (based on the orientation of the emitter icon and indicated by the icon arrow) depends on the viewport in which you create the icon. Generally, the particles spray toward you when created in an orthographic viewport, or spray upward when created in a Perspective viewport.

3. Adjust the various parameters to alter the spray effect.

**Interface**

Note: This section describes the Particle Formation group in the Basic Parameters rollout, and the Particle Motion group in the Particle Generation rollout. These are the only controls unique to Super Spray. The other Super Spray rollouts and their contents are identical with those in Particle Array, except that Object Fragments and associated settings are not available on the Particle Type rollout. See *PArray Particle System* (page 2–256) for details or choose from the following list for rollout information.

*Particle Generation Rollout* (page 2–260)
*Particle Type Rollout* (page 2–262)
*Rotation and Collision Rollout* (page 2–268)
*Object Motion Inheritance Rollout* (page 2–269)
*Bubble Motion Rollout* (page 2–270)
*Particle Spawn Rollout* (page 2–271)
*Load/Save Presets Rollout* (page 2–274)

**Basic Parameters rollout > Particle Formation group**

<table>
<thead>
<tr>

</tbody>
</table>

These items control the direction and spread of particles.

**Off Axis**—Affects the angle of the particle stream off the Z axis (along the plane of the X axis).

**Spread**—Affects the spread of the particles away from the emission vector (along the plane of the X axis).

**Off Plane**—Affects the angle of emission about the Z axis. This has no effect if Off Axis is set to 0.

**Spread**—Affects the spread of the particles about the Off Plane axis. This has no effect if Off Axis is set to 0.

**Particle Generation rollout > Particle Motion group**

**Speed**—The speed of the particle at birth, in units per frame.
Variation—Applies a percentage of variation to the speed of emission for each particle.

Blizzard Particle System

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > Blizzard

Create menu > Particles > Blizzard

This is an advanced version of the original Snow particle system.

Tip: To animate particles following a path through space, use the Path Follow space warp (page 2–71).

Procedures

To create a blizzard particle system:

1. On the Create panel, make sure the Geometry button is active and Particle Systems is chosen in the object category list, then click Blizzard.
2. Drag in a viewport to create the Blizzard emitter; see Creating a Particle Emitter (page 2–239).
   The icon appears as a plane with a perpendicular line pointing in the direction of emission.
3. Adjust the various parameters on the command panel.

Interface

This section describes the Display Icon group in the Basic Parameters rollout, the Particle Motion group in the Particle Generation rollout, and the Material Mapping and Source group in the Particle Type rollout. These are the only controls unique to Blizzard. The other Blizzard rollouts and their contents are identical with those in Particle Array, except that Object Fragments and associated settings are not available on the Particle Type rollout. See PArray (page 2–256) for details or choose from the following list for rollout information.

- Particle Generation Rollout (page 2–260)
- Particle Type Rollout (page 2–262)
- Rotation and Collision Rollout (page 2–268)
- Object Motion Inheritance Rollout (page 2–269)
- Particle Spawn Rollout (page 2–271)
- Load/Save Presets Rollout (page 2–274)
The emitter specifies the location where particles are generated in the scene. It has a geometry you can display in viewports, but it isn’t renderable.

The emitter is displayed as a rectangle with a vector pointing out of one side. The vector shows the direction in which the system emits particles.

You set emitter parameters on the particle system’s Basic Parameters rollout, in the Display Icon group.

**Width and Length**—You implicitly set the initial value of these parameters when you drag in a viewport to create the emitter. You can adjust the values on the rollout.

The space occupied by the particle system at any given time is the result of a combination of its initial parameters (such as size of the emitter, and speed and variation of emission) and any space warps that have been applied.

**Emitter Hidden**—Hides the emitter in viewports. When off, the emitter is displayed in viewports. The emitter is never rendered. Default=off.

**Particle Generation rollout > Particle Motion group**

Specifies the number, size, and motion of particles.

**Speed**—The speed of the particle at birth, in units per frame.

**Variation**—Applies a percentage of variation to the speed of emission for each particle.
**Tumble**—Amount of random rotation of the particles.

**Tumble Rate**—Speed at which the particles rotate.

Particle Type rollout > Mat’l Mapping and Source group

**Emitter Fit Planar**—Maps particles at birth, based on their point of emission from the rectangular Blizzard emitter icon. The UV range of the mapped material runs from 0 to 1 over the width and length of the emitter.

---

**PCloud Particle System**

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > PCloud

Create menu > Particles > PCloud

Use the PCloud (or Particle Cloud) particle system when you want a "cloud" of particles that fill a specific volume. PCloud can provide a flock of birds, a starfield, or a troupe of soldiers marching over terrain. You can confine the particles using basic supplied volumes of a box, sphere, or cylinder, or you can use any renderable object in the scene as a volume as long as that object has depth. Two-dimensional objects do not work with PCloud.

Tip: There is no automatic way to hide the object chosen as the object-based emitter. Hide it by using Hide Selected on the Display panel, or by applying a Hide key in Track View.

---

**PCloud viewport icon**

PCloud viewport icon (default emitter)
Chapter 11: Space Warps and Particle Systems

Chapter 11: Space Warps and Particle Systems

Procedure

To create a particle cloud:

1. On the Create panel, make sure the Geometry button is active and Particle Systems is chosen in the object category list, then click PCloud.

2. Drag in a viewport to create the PCloud emitter; see Creating a Particle Emitter (page 2–239).

   Adding a PCloud emitter works the same way as creating a box primitive: First drag out the length and width, then release the mouse button and move the mouse vertically to set the height, and then click to finish.

3. Adjust the various parameters on the command panel.

Interface

This section describes the Object-Based Emitter, Particle Formation, and Display Icon groups in the Basic Parameters rollout, and the Particle Motion group in the Particle Generation rollout. These are the only controls unique to PCloud. The other PCloud rollouts and their contents are identical with those in Particle Array, except that Object Fragments and associated settings are not available on the Particle Type rollout. See PArray (page 2–256) for details or choose from the following list for rollout information.

- Particle Generation Rollout (page 2–260)
- Particle Type Rollout (page 2–262)
- Rotation and Collision Rollout (page 2–268)
- Object Motion Inheritance Rollout (page 2–269)
- Bubble Motion Rollout (page 2–270)
- Particle Spawn Rollout (page 2–271)
- Load/Save Presets Rollout (page 2–274)

The emitter appears with a letter "C" representing the particle cloud.
Basic Parameters rollout

Object-Based Emitter group

This button lets you select a renderable mesh object to use as a particle emitter. This object is used only when the Object-Based Emitter option is chosen in the Particle Formation group.

Pick Object—Click this, and then select a renderable mesh object to be used as a custom emitter.

Object—Displays the name of the picked object.

Particle Formation group

These options let you specify the shape of the emitter.

Box Emitter—Chooses a box-shaped emitter.

Sphere Emitter—Chooses a sphere-shaped emitter.

Cylinder Emitter—Chooses a cylindrical emitter.

Object-Based Emitter—Chooses the object selected in the Object-Based Emitter group.

Note: With regard to animation of the object-based emitter, the particles will properly fill a deformed object at frame 0, but they can't stay with the emitter while it's moving. If the emitter moves in a straight line, this can give the appearance of the cloud moving with the emitter.

Display Icon group

These options let you adjust the dimensions of the emitter icon when a custom object is not used as an emitter. When a custom object is used you can still resize the "Fill" icon using these options.

Rad/Len—Adjusts the radius of a spherical or cylindrical icon, and the length of a box icon.

Width—Sets the width of a box emitter.

Height—Sets the height of a box or cylindrical emitter.

Emitter Hidden—Hides the emitter.
Particle Generation rollout > Particle Motion group

**Speed**—The speed of the particle at birth along the normal, in units per frame.

**Note:** For the correct volume effect, Speed should be set to 0.

**Variation**—Applies a percentage of variation to the speed of emission for each particle.

**Random Direction**—One of three options that affect the direction of the particles. This option emits particles in random directions.

**Direction Vector**—Specifies the direction of the particles by a vector defined by the three X, Y, and Z spinners.

**X/Y/Z**—Displays the particle direction vectors.

**Reference Object**—Emits particles in the direction of the local Z axis of a specified object.

**Object**—Displays the name of the picked object.

**Pick Object**—Click this, and then select an object in the scene to use as a reference object. This button is available only when you choose Reference Object.

**Variation**—Applies a percentage of variation to the direction when you choose either the Direction Vector or Reference Object option. This spinner is unavailable and has no effect when you choose Random Direction.

---

**PArray Particle System**

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > PArray

Create menu > Particles > PArray

Basket used as a distribution object for random particles over its surface

The PArray (Particle Array) particle system provides two types of particle effects:

- You can use it to emit particles using a selected geometric object as the emitter template (or pattern) for the emission. This object is referred to here as the distribution object.
To set up a particle array:

1. Create an object that will become the distribution object, providing the emitter pattern (or exploded object) for the particle array.

2. On the Create panel, make sure the Geometry button is active and Particle Systems is chosen in the object category list, then click PArray.

3. Drag anywhere in a viewport to create the particle-system object; see *Creating a Particle Emitter* (page 2–239).

4. On the Basic Parameters rollout, click Pick Object, and then click the object to use as the distribution object.

5. Adjust the various options in the Particle Array rollouts to achieve the effect you want.

   The distribution object can be any object containing renderable faces. The particle-system object does not appear in the rendered scene. Its placement, orientation or size in the scene has no influence on the particle effect. To access the Particle Array parameters after creation, open the Modify panel and select the particle-system object (or click any visible particles in the viewport). To transform or otherwise modify the distribution object, select the distribution object itself.

   Also, you can share a single distribution object among more than one particle-system object. The distribution object merely provides the template for the particles, which are actually generated by the particle system.

Example: To assign three different mapped materials to fragments:

1. Apply mapping coordinates to the distribution object, either by turning on Generate Mapping Coords, if necessary, or by applying a *UVW Map* modifier (page 1–922).

2. Assign a *Multi/Sub-Object material* (page 2–1594) to the distribution object.

3. Set up the first three sub-materials to be mapped materials.
4. Select the PArray icon.

5. On the Particle Type rollout in the Mat’l Mapping And Source group, choose Picked Emitter.

6. In the Particle Type rollout > Particle Types group, turn on Object Fragments.

7. Make sure the three spinners in the Fragment Materials group are set to 1, 2, and 3, respectively (or match the numbers with the sub-materials you’ve assigned in your multi/sub-object material).

Tip: Using a complex distribution object for object-fragment particles can really slow down viewport interaction. You can use a simple stand-in object as the distribution object, and then later use the File/Replace command to replace the distribution object with a more complex object of the same name.

Interface

Basic Parameters Rollout (PArray) (page 2–258)
Particle Generation Rollout (page 2–260)
Particle Type Rollout (page 2–262)
Rotation and Collision Rollout (page 2–268)
Object Motion Inheritance Rollout (page 2–269)
Bubble Motion Rollout (page 2–270)
Particle Spawn Rollout (page 2–271)
Load/Save Presets Rollout (page 2–274)

Basic Parameters Rollout (PArray)

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > PArray > Basic Parameters rollout

The items on the Basic Parameters rollout let you create and adjust the size of the particle system, and pick the distribution object. In addition, they let you specify the initial distribution of the particles in relation to the geometry of the distribution object, and the initial velocity of the particles from the distribution object. From here, you can also specify how the particles appear in the viewport.

Object-Based Emitter group

Pick Object—After you create the particle-system object, the Pick Object button becomes available. Click this button, and then click to select an object in your scene. The selected object becomes the
object-based emitter, and is used either as the source geometry over which particles form, or the source geometry used to create particles that appear to be fragments of the object.

**Object text field**—Displays the name of the picked object.

**Particle Formation group**

These options determine how standard particles are initially distributed over the surface of the object-based emitter. These controls are available only when the picked object is used as a distribution grid for standard particles, MetaParticles, or instanced geometry; see *Particle Type rollout (page 2–262)*. When Object Fragments is chosen in the Particle Type rollout, these controls are unavailable.

- **Over Entire Surface**—Emits particles randomly over the entire surface of the object-based emitter. This is the default choice.
- **Along Visible Edges**—Emits particles randomly from the visible edges of the object.
- **At All Vertices**—Emits particles from the vertices of the object.
- **At Distinct Points**—Places a specified number of emitter points randomly over the surface of the object.
- **Total**—Specifies the number of emitter points used when At Distinct Points is chosen.
- **At Face Centers**—Emits particles from the center of each triangular face.
- **Use Selected SubObjects**—With mesh-based emitters, and to a limited extent with patch-based emitters, limits the source of the particle stream to the sub-object selection passed up the modifier stack in the object-based emitter. For example, if your emitter object is a cylinder converted to an editable mesh, and the top cap of that cylinder is selected at the Face or Polygon sub-object level, if Use Selected SubObjects is on and Particle Formation group > At Face Centers is on, the particles will stream only from the top cap of the cylinder. Default=off.

The type of particle formation you specify determines the type of sub-object geometry used, as follows:

- **Over Entire Surface**—Faces
- **Along Visible Edges**—Edges
- **At All Vertices**—Vertices
- **At Distinct Points**—Faces
- **At Face Centers**—Faces

If you’ve converted your object to an editable mesh, and selected different sub-object sections of it with vertex, edge, and face selection, as you switch particle formation options, you’ll see the particles emit from different areas of the object.

**Note:** Use Selected SubObjects is applicable to patch object emitters only at the patch and element sub-object levels, and is not applicable NURBS objects used as emitters.

**Tip:** You can best see the emission patterns by first setting Speed on the Particle Generation rollout > Particle Motion group to 0. Move to a frame in which the particles appear, and then choose the various particle formation options.

**Display Icon group**

Adjusts the display of the particle-system icon in the viewports. (The particle-system icon is usually called the "emitter." In this case, however, it doesn’t actually emit particles, so we’re avoiding the term.)

- **Icon Size**—Sets the overall size of the icon, in units.
- **Icon Hidden**—When on, the PArray icon is hidden in the viewports. Note that the icon does not render, in any case. Default=off.
Viewport Display group

Specifies how the particles are displayed in the viewports.

**Dots**—Displays the particles as dots.

**Ticks**—Displays the particles as crosses.

**Mesh**—Displays the particles as mesh objects. This results in slower viewport redraws.

**BBox**—For instanced geometry only, this displays each instanced particle, whether a single object, a hierarchy, or a group, as a bounding box.

**Percentage of Particles**—This spinner specifies the number of particles displayed in the viewports as a percentage of the number of rendered particles. Default=10 percent.

Set the display percentage to 100 percent if you want to see the same number of particles as will be rendered in your scene. However, this can considerably slow viewport display.

Particle Generation Rollout

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > SuperSpray/Blizzard/Parray/PCloud > Particle Generation rollout

Select a SuperSpray/Blizzard/Parray/PCloud emitter. > Modify panel > Particle Generation rollout

Items on this rollout control when and how quickly particles form, how particles move, and the size of the particles over time.

Particle Quantity group

In this group, you can choose one of two methods by which the number of particles is determined over time. These settings are unavailable if you set Particle Type (in the Particle Type rollout (page 2–262)) to Object Fragments.
**Use Rate**—Specifies a fixed number of particles emitted per frame. Use the spinner to set the number of particles formed per frame.

**Use Total**—Specifies a total number of particles formed over the life of the system. Use the spinner to set the number of particles formed per frame.

The life of the system, in frames, is specified by the Life spinner in the Particle Timing group, described later in this topic.

Tip: Generally, Use Rate is best for a continuous flow of particles, like a trail of pixie dust, while Use Total is better for bursts of particles over a short period of time.

**Particle Motion group**

These spinners control the initial particle velocity, which is directed along the surface, edge, or vertex normals (interpolated for each emitter point).

**Speed**—The velocity of the particle at birth, along the normal, in units traveled per frame.

**Variation**—Applies a percentage of variation to the speed of emission for each particle.

**Divergence**—Applies an angular degree of variation by which each particle’s velocity can vary from the emitter normal.

Note: The initial direction for a fragment cluster is the normal of the cluster’s seed face. Clusters are created by choosing a single face (the seed face), and then creating a cluster outward from that face, depending on the method chosen in the Object Fragment Controls group on the Particle Type rollout.

**Particle Timing group**

These options specify when particle emission starts and stops, and the lifespan of the individual particles.

**Emit Start**—Sets the frame at which particles begin to exist in the scene.

**Emit Stop**—Sets the last frame at which particles are emitted. This setting has no effect if you choose the Object Fragments particle type.

**Display Until**—Specifies the frame at which all particles will disappear, regardless of other settings.

**Life**—Sets the lifespan in number of frames of each particle from the frame of creation.

**Variation**—Specifies the number of frames by which the life of each particle can vary from the norm.

**Subframe Sampling**—Turning on any of the three check boxes below helps avoid particle "puffing" by sampling particles at a much higher subframe resolution, instead of the relatively coarse frame resolution. Depending on your needs, you can do this over time, over motion, or over rotation. "Puffing" is the effect of emitting separate "puffs" or clusters of particles, rather than a continuous stream. This effect is especially noticeable when the emitter is animated.

- **Creation Time**—Enables the addition of a time offset to the equations of motion that prevents puffing in time. This setting has no effect with the Object Fragments particle type. Default=on.

- **Emitter Translation**—If the object-based emitter is moving in space, particles are created at integral times at positions along the geometry’s path between renderable positions. This prevents puffing in space. This setting has no effect if Object Fragment particle type is on. Default=on.

- **Emitter Rotation**—If the emitter is rotating, turn this on to avoid puffing and produce smooth spiral effects. Default=off.

**Important:** Each additional subframe sampling check box that you turn on progressively increases the necessary computation. In addition, the methods are listed in order of least amount of computation.
to most. Thus, Emitter Rotation is more costly than Emitter Translation, which is more costly than Creation Time.

Particle Size group
These spinners specify the size of the particles.

Size—This animatable parameter specifies the target size for all particles in the system, depending on the type of particle:

- **Standard Particles**—The major dimension of the particle.
- **Constant**—The dimension, in rendered pixels, of a Constant type of particle.
- **Object Fragments**—No effect.

Variation—The percentage by which the size of each particle may vary from the norm. This is applied to the Size value. Use this parameter to get a realistic mix of large and small particles.

Grow For—The number of frames over which the particle grows from being very small to the Size value. The result is subject to the Size/Variation value, since Grow For is applied after Variation. Use this parameter to simulate natural effects such as bubbles growing as they reach the surface.

Fade For—The number of frames over which the particle will shrink to 1/10th its Size setting prior to its death. This is also applied after Variation. Use this parameter to simulate natural effects such as sparks fading to ash.

Uniqueness group
By changing the Seed value in this spinner, you achieve different results using otherwise identical particle settings.

New—Randomly generates a new seed value.

Seed—Sets a specific seed value.
**Particle Type Rollout**

**Interface**

### Particle Types group

These options specify one of four categories of particle type. Depending on which option you choose, different controls become available in the lower portion of the Particle Type rollout.

- **Standard Particles**—Uses one of several standard particle types, such as triangle, cube, tetra, and so on.
- **MetaParticles**—Uses Metaball particles. These are particle systems in which the individual particles blend together in blobs or streams.
- **Object Fragments**—Creates particles out of fragments of an object. Object Fragments is available only with Particle Array. Choose it when you want to fracture the particle emitter object and use the pieces as particles. This option is useful for animating explosions and shattering collisions.
  
  The fragments are created at the Emit Start frame. The Use Rate, Use Total, Emit Stop, and Particle Size parameters are unavailable.

- **Instanced Geometry**—Generates particles that are instances of either an object, a linked hierarchy of objects, or a group. The object is selected in the Instancing Parameters group on the Particle Type rollout.

  Choose Instanced Geometry when you want particles to be identical instances of another object in your scene. Instanced geometry particles are extremely effective for creating crowds, flocks, or flows of very detailed objects. Here are a few examples:

  - Instance a red blood cell and use Super Spray to animate blood flowing in an artery.
  - Instance a bird and use Particle Cloud to animate a flock of birds flying.
  - Instance a rock and use Particle Cloud to animate an asteroid field.

  **Note:** Only one type of particle can be used for the particle system. However, you can have more than one particle array bound to a
single object, and each particle array can emit a different type of particle.

Tip: Image motion blur, described in *Object Properties (page 1–117) > Motion Blur group*, is known not to work properly with instanced particles. Use object motion blur with instanced particles, or use image motion blur with standard particles.

**Standard Particles group**

When you choose Standard Particles in the Particle Types group, the options in this group become available. Choose one of the following options to specify the particle type:

- **Triangle**—Renders each particle as a triangle. Use Triangle particles with noise opacity for steam or smoke.

- **Cube**—Renders each particle as a cube.

- **Special**—Each particle consists of three intersecting 2D squares. These are effective when you use a face-map material, described in *Shader Basic Parameters Rollout (page 2–1466)*, optionally along with an opacity map, to create the effect of a three-dimensional particle.

- **Facing**—Renders each particle as a square that always faces the view. Use with an appropriate opacity map for bubbles or snowflakes.

- **Constant**—Provides a particle that remains the same size, in pixels, specified in the Size spinner. This size never changes, regardless of its distance from the camera.

- **Tetra**—Renders each particle as a mapped tetrahedron. Use Tetra particles for raindrops or sparks.

- **SixPoint**—Renders each particle as a six-pointed, two-dimensional star.

- **Sphere**—Renders each particle as a sphere.

**MetaParticle Parameters group**

When you choose the MetaParticles option in the Particle Types group, the options in this group become available, and metaballs are used as particles. Metaparticles take extra time to render but are very effective for spraying and flowing liquid effects.

- **Tension**—Determines the tightness of the particles, with regard to their tendency to blend with other particles. The higher the Tension, the harder the blobs, and the harder it is for them to merge.

- **Variation**—Specifies the percent of variation of the Tension effect.

- **Evaluation Coarseness**— Specifies how accurately the metaparticle solution is calculated. The higher the coarseness values, the less calculation. However, if the coarseness is too high, there may be little or no metaparticle effect at all. Conversely, if the coarseness is set too low, the time for calculation can become extremely long.

- **Render**—Sets the coarseness for metaparticles in the rendered scene. This option is unavailable when Automatic Coarseness is on.

- **Viewport**—Sets the coarseness for the viewport display. This option is unavailable when Automatic Coarseness is on.

- **Automatic Coarseness**—A general rule is to set the Coarseness value between 1/4 and 1/2 the size of the particles. When this item is on, the rendering coarseness is automatically set, based on the size
of the particles, and the viewport coarseness is set to about twice that of the rendering coarseness.

**One Connected Blob**—When off (the default), all particles are calculated; when on, a shortcut algorithm is used that calculates and displays only those particles that are adjoining or contiguous to each other.

*Note:* One Connected Blob mode speeds particle calculations, but you should use it only when your metaparticles form one connected blob, as the label indicates. That is, all particles' blobs must be touching. For example, if you were to use One Connected Blob on a stream of particles containing a mass of 10 contiguous particles followed by a space, then 12 contiguous particles followed by another space, and finally 20 contiguous particles, one of the particles will be chosen, and only the mass connected to that particle will be displayed and rendered.

*Tip:* When in doubt, leave this option off. If you think all your particles are contiguous and want to save time, turn on One Connected Blob, and then display various frames to see if everything appears.

**Object Fragment Controls group**

With a particle array, when you choose the Object Fragments particle type, the items in this group become available, and the object-based emitter is exploded into fragments, rather than being used to distribute particles.

*Note:* To see the fragments in the viewports, choose Mesh in the Viewport Display group near the bottom of the Basic Parameters rollout (page 2–258).

The items in this group include a Thickness spinner, along with three option buttons that determine how the fragments are formed.

*Tip:* There is no automatic way to hide the distribution object that explodes into fragments. To create the illusion that an object is exploding, you must either set the original object to be invisible at the start of the explosion, as described in *Add Visibility Track* (page 2–556), or move or scale the original object so it doesn’t remain in view.

**Thickness**—Sets the thickness of the fragments. At 0, the fragments are single-sided with no thickness. When greater than 0, the fragments are extruded, at fragmentation time, by the amount specified. The outer and inner surfaces of the fragment use identical smoothing, which is picked up from the object-based emitter. The edges of the fragments are not smoothed.

The three options that follow specify how the object fragments.

- **All Faces**—Each face of the object becomes a particle. This results in triangular particles.
- **Number of Chunks**—The object breaks into irregular fragments. The Minimum spinner, below, specifies the minimum number of fragments that will appear. The method of calculating the chunks may result in more fragments than specified.
- **Minimum**—Determines a number of "seed" faces in the geometry. Each seed face collects connecting faces surrounding it until all available faces are exhausted. Any leftover faces become unique particles, thus increasing the minimum number of fragments.
- **Smoothing Angle**—The fragments are broken based on the angles between face normals, as specified in the Angle spinner. Generally, the higher the Angle value, the fewer the number of fragments.
- **Angle**—Sets the amount of smoothing angle.
Instancing Parameters group

These options are used when you specify Instanced Geometry in the Particle Types group. They let you generate each particle as an instance of either an object, a linked hierarchy of objects, or a group.

Note: Instanced objects can be animated, providing the animation incorporates one or more of the following types:

- Animation of object geometry parameters, such as a sphere’s Radius setting.
- Animation of object-space modifiers, such as the Angle setting of a Bend modifier (page 1–560).
- Transform animation of a hierarchical object’s children. Transform animation of the top-level parent and non-hierarchical objects is not supported. For example, if you use the toolbar Select and Rotate function (page 1–439) to animate a box rotating, and then use the box as instanced geometry with a particle system, the system will not use instanced box’s keyframed animation.

Object—Displays the name of the picked object.

Pick Object—Click this, and then select an object in the viewport to be used as a particle. If you select an object that’s part of a hierarchy and Use Subtree Also is on, then the picked object and its children become a particle.

If you pick a group, all objects in the group are used as a particle.

Use Subtree Also—Turn this on when you want to include the linked children of the picked object in the particle. If the picked object is a group, all children of the group are included. Note that you can turn this on or off at any time to alter the particles.

Animation Offset Keying—Because the instanced objects can be animated, the options here let you specify the timing of the animations for the particles.

None—Each particle duplicates the timing of the original object. As a result, the animation of all particles will be identically timed.

Birth—The firstborn particle is an instance of the current animation of the source object at the moment of that particle’s birth. Each subsequent particle then uses the same start time for the animation. For example, if the animation of the source object is a bend from 0 to 180 degrees,
and the first particle is born at frame 30, when the object is at 45 degrees, then that particle, and all subsequent particles will be born starting at a bend of 45 degrees.

**Random**—This option is the same as None when Frame Offset is set to 0. Otherwise, each particle is born using the same animation as the source object at the time of birth, but with a random offset of frames, based on the value in the Frame Offset spinner.

**Frame Offset**—Specifies an offset value from the current timing of the source object.

**Mat'l Mapping and Source group**

Specifies how a mapped material affects the particles, and lets you specify the source of the material assigned to the particles. A detailed description of how materials affect particles is in the topic Using Mapped Materials with Particle Systems (page 2–240).

**Time**—Specifies the number of frames from the birth of the particle that it takes to complete one mapping of the particle.

**Distance**—Specifies the distance, in units, from the birth of the particle that it takes to complete one mapping of the particle.

Note: Tetra particles are an exception. They always have their own local mapping from head to tail, as described in the following section.

Get Material From—Updates the material carried by the particle system, using the source specified by the option buttons below this button.

**Important:** Remember to click Get Material From whenever you choose a different source option button, or whenever you assign a new material to the specified source. Only a single material (or multi/sub-object material) is carried by the particle-system object at any time. Thus, when you change sources, you actually overwrite the currently assigned material with an instance of the source material.

**Icon**—The particles use the material currently assigned to the particle system icon.

Note: The Time and Distance options are available only when you choose this option.

**Picked Emitter**—The particles use the material assigned to the distribution object.

**Instanced Geometry**—The particles use the material assigned to the instanced geometry. This option is available only when you choose Instanced Geometry in the Particle Types group.

**Important:** When you turn on either Picked Emitter or Instanced Geometry, an instance of the material from the chosen source is copied to the emitter icon, overwriting the material originally assigned to the icon. Thus, if you've assigned a material to the particle emitter, and then switch to Picked Emitter, the material originally assigned to the icon is replaced by an instance of the material carried by the picked object. If you then return to the Icon option, the particle system does not revert to the material that was assigned the icon, but retains the material taken from the picked object.

Fragment Materials group

These spinners let you assign different material ID numbers to outside surfaces, the edges and the back sides of fragment particles. You can then assign different materials to the front, edge and back of the fragments by using a multi/sub-object material.

**Outside ID**—Specifies which face ID number is assigned to the outside faces of the fragments. This spinner defaults to 0, which is not a valid ID number, forcing the outside of the particle fragments to use whatever material is currently assigned to the associated faces. Thus, if your distribution object already has several submaterials assigned to its outer faces, these materials are retained by using ID 0. If you want a single,
specific submaterial, you can assign it by changing the Outside ID number.

**Edge ID**—Specifies which submaterial ID number is assigned to the edges of the fragments.

**Backside ID**—Specifies which submaterial ID number is assigned to the back sides of the fragments.

**Rotation and Collision Rollout**

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > SuperSpray/Blizzard/Parray/PCloud > Rotation and Collision rollout

Select a SuperSpray/Blizzard/Parray/PCloud emitter. > Modify panel > Rotation and Collision rollout

Particles often move at high rates of speed. In such cases, you might want to add motion blur to the particles to enhance their motion. Also, real-world particles typically rotate as they move, and collide with each other.

The options on this rollout affect the rotation of the particles, provide motion blur effects, and control inter-particle collisions.

**Interface**

**Spin Speed Controls group**

**Spin Time**—The number of frames for one rotation of a particle. If set to 0, no rotation takes place.

**Variation**—The percent of variation of the Spin Time.

**Phase**—Sets the initial particle rotation, in degrees. This has no meaning for fragments, which always begin with zero rotation.

**Variation**—The percent of variation of the Phase.
Spin Axis Controls group

These options determine the spin axis for the particles, and provide a partial method of applying motion blur to the particles.

**Random**—The spin axis for each of the particles is random.

**Direction of Travel/Mblur**—(Not available with the Blizzard particle system.) Rotates the particles about a vector formed by the direction in which they’re moving. This option also lets you apply a form of motion blur to the particles by using the Stretch spinner. For further information, see *Achieving Particle Motion Blur* (page 2–240).

**Stretch**—When greater than 0, the particles stretch along the travel axis, depending on their speed. Specifically, the Stretch value specifies the percent of their length per each unit of the Speed setting (in the Particle Motion group). Thus, if you set Stretch to 2 while Speed is set at 10, the particles are stretched 20 percent longer than their original size along the axis of their travel. This spinner is available only when you choose Direction of Travel/Mblur.

Note: For best results when using Stretch, you should also assign the Particle MBlur map as an opacity map of the material assigned to the particle system.

**User Defined**—Uses a vector defined in the three X, Y, and Z axis spinners.

**X/Y/Z Axis**—Specifies the spin vector of the X, Y, or Z axis, respectively. These spinners are available only when User Defined is chosen.

**Variation**—The amount, in degrees, by which the spin axis of each particle may vary from the specified X Axis, Y Axis, and Z Axis settings. This spinner is available only when you choose User Defined.

Interparticle Collisions group

These options enable collisions between particles, and control how the collisions occur. Note that this involves intensive calculation, particularly when large numbers of particles are involved.

**Enable**—Enables inter-particle collisions in the calculation of the particle movements.

**Calc Intervals Per Frame**—The number of intervals per rendering interval, during which an inter-particle collision test is conducted. The higher the value, the more accurate the simulation, but the slower the simulation will run.

**Bounce**—The degree to which speed is recovered after a collision.

**Variation**—The percentage of random variation of the Bounce value, applied to the particles.

Object Motion Inheritance Rollout

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > SuperSpray/Blizzard/Parray/PCloud > Object Motion Inheritance rollout

Select a SuperSpray/Blizzard/Parray/PCloud emitter. > Modify panel > Object Motion Inheritance rollout

Each particle’s position and direction of movement are determined by the position and orientation of the emitter at the time the particle is created. If the emitter is moving through the scene, particles are scattered along the emitter’s path.

Use these options to affect the motion of the particles by the motion of the emitter.

**Procedure**

**Example: To observe object motion inheritance:**

1. Create a Super Spray particle system.
2. Animate the emitter moving sideways (perpendicular to the direction of the particle stream) between frames 1 and 15.
3. Play the animation while observing it from the Top viewport.

The emitter stops at frame 15, while the particles it has emitted up to that point continue moving along the diagonal between the emitter's path and that of the particles. The remaining particles move straight out from the emitter.

4. On the Object Motion Inheritance rollout, set Influence to 50.

5. Play the animation again.

This time, only some of the particles inherit the emitter’s motion, while the rest move straight out from the emitter. Note that the latter form a diagonal stream because each particle emerges at a subsequent point on the emitter path.

Interface

- **Influence**—The percent of particles that inherit the motion of the object-based emitter at the moment of particle formation. For example, when this is set at 100 (the default), all particles travel along with a moving object; when it’s set at 0, none of the particles are affected by the translation of the object and fall behind its movement.

- **Multiplier**—Modifies the amount by which the emitter motion affects the particle motion. This can be a positive or negative number.

- **Variation**—Provides a percentage of variation of the Multiplier value.

### Bubble Motion Rollout

Bubble motion provides the wobbling effect you see in bubbles rising underwater. Typically, it’s used when the particles are set to rise in thin streams. Bubble motion is similar to a waveform, and the Bubble Motion parameters let you adjust the amplitude, period, and phase of the bubble "wave."

Note: The bubble motion is not affected by space warps, so you can use a space warp to control the direction of the particle flow without altering the local, wobbling bubble effect.

Tip: InterParticle Collisions, Deflector Binding, and Bubble Noise do not get along well together. Particles may leak through the deflector when these three are used together. Instead of bubble motion, use animated mapping. Use facing particles with an animated map of a bubble, where the bubble is smaller than the map size. The bubble is animated moving around the map. This simulates bubble motion at the map level.

Interface

- **Amplitude**—The distance the particle moves off its usual velocity vector as it travels.
Variation—The percent of Amplitude variation applied to each particle.

Period—The cycle time for one complete oscillation of a particle through the bubble "wave." A recommended value might be 20 to 30 intervals. Note: Bubble motion is measured in time, not in rate, so a very large Period value means the motion takes a long time to complete. Thus, there is no motion, effectively. Period is therefore set to a very large default value so that the default motion of this type is none.

Variation—The percent of Period variation for each particle.

Phase—The initial displacement of the bubble pattern along the vector.

Variation—The percent of Phase variation for each particle.

Particle Spawn Rollout

Create panel > Geometry button > Choose Particle Systems from the drop-down list. > Object Type rollout > SuperSpray/Blizzard/Parray/PCloud > Particle Spawn rollout

Select a SuperSpray/Blizzard/Parray/PCloud emitter. > Modify panel > Particle Spawn rollout

The options on the Particle Spawn rollout let you specify what happens to particles when they die, or when they collide with a particle deflector. Using the options on this rollout, you can have particles generate additional generations of particles upon collision or death.

Particle Spawning Effects group

Choose one of these options to determine what happens to the particles at either collision or death.

None—Uses none of the spawning controls, and the particles act as they normally would. That is, upon collision, they either bounce or stick,
depending on Particle Bounce settings in the deflector, and on death they disappear.

**Die After Collision**—Particles disappear when they strike a deflector to which they’re bound, such as the SDeflector.

**Persist**—The life, in frames, that the particle will persist after the collision. Setting this to 0 (the default) causes particles to vanish immediately after the collision.

**Variation**—Varies the Persist value of each particle, when Persist is greater than 0. This lets you "feather" the dying off of particle density.

**Spawn on Collision**—Spawn effects take place upon collision with a bound deflector.

**Spawn on Death**—Spawn effects take place at the end of each particle’s life.

**Spawn Trails**—Particles are spawned from existing particles at each frame of that particle’s life. The Multiplier spinner specifies the number of particles that are spawned from each particle. The base direction of the spawned particles is opposite that of the parent’s velocity. The Scale, Direction, and Speed Chaos factors are applied to that base direction.

Note: If the Multiplier is greater than 1, at least one of the three Chaos factors must be greater than 0 in order to see the additional spawned particles. Otherwise, the multiples will occupy the same space.

**Warning:** This option can produce many particles. For best results, begin by setting Particle Quantity on the Particle Generation rollout to Use Rate and to 1.

**Spawns**—The number of spawns beyond the original particle generation. For example, if this is set to 1, and you’re spawning at death, one spawning will occur beyond the original lifespan of each particle.

**Affects**—Specifies the percentage of particles that will spawn. Reducing this reduces the number of particles that produce spawned particles.

**Multiplier**—Multiplies the number of particles spawned at each spawning event.

**Variation**—Specifies a percentage range by which the Multiplier value will vary, frame by frame.

**Direction Chaos group**

**Chaos**—Specifies the amount by which the direction of the spawned particle can vary from the direction of the parent particle. A setting of 0 means no variance. A setting of 100 causes the spawned particle to travel in any random direction. A setting of 50 causes the spawned particle to deviate from its parent’s path by up to 90 degrees.

**Speed Chaos group**

These options let you vary the spawned particles’ speed randomly in relation to their parents’ speed.

**Factor**—This is the range of a percentage of change in the speed of the spawned particle relative to its parent. A value of 0 means no change.

**Slow**—Applies the speed factor randomly to slow the speed of the spawned particles.

**Fast**—Randomly speeds up particles based on the speed factor.

**Both**—Some particles speed up, while others slow down, based on the speed factor.

**Inherit Parent Velocity**—Spawned particles inherit the speed of their parents, in addition to the effect of the speed factor.

**Use Fixed Value**—Uses the Factor value as a set value, rather than as a range applied randomly to each particle.
Particle Spawn Rollout

Scale Chaos group

Factor—Determines a random percentage range of scaling of the spawned particles relative to their parents, and dependent on the options below.

Down—Randomly scales down spawned particles to be smaller than their parents, based on the Factor value.

Up—Randomly scales up spawned particles to be larger than their parents.

Both—Scales spawned particles both larger and smaller than their parents.

Use Fixed Value—Uses the Factor value as a fixed value, rather than a range of values.

Lifespan Value Queue group

These options let you specify a list of alternative lifespan values for each spawned generation of particles. The spawned particles use these lifespans rather than the lifespan specified for the original particles in the Life spinner on the Particle Generation rollout (page 2–260).

**List window**—Displays a list of lifespan values. The first value on the list is used for the first generation of spawned particles, the next value is used for the next generation, and so on. If there are fewer values on the list than there are spawnings, then the last value is used repeatedly for all remaining spawnings.

**Add**—Adds the value in the Lifespan spinner to the list window.

**Delete**—Deletes the currently highlighted value in the list window.

**Replace**—Lets you replace a value in the queue with a value in the Lifespan spinner. To use, first place a new value in the Lifespan spinner, then select the value in the queue you want to replace, and click the Replace button.

Object Mutation Queue group

The options in this group let you switch between instanced-object particles with each spawning (as set with the Spawns spinner). These options are available only if Instanced Geometry is the current particle type.

**List window**—Displays a list of objects to be instanced as particles. The first object on the list is used for the first spawning, the second for the second spawning, and so on. If there are fewer objects on the list than there are spawnings, then the last object on the list is used for all remaining spawnings.
Pick—Click this, and then select an object in the viewport to add to the list. Note that the type of object you use is based on the settings in the Instancing Parameters group of the Particle Type rollout. For example, if you’ve turned on Subtree in that group, you can pick object hierarchies. Likewise, if you’ve picked a group, you can use groups as your spawned particles.

Delete—Deletes the currently highlighted object in the list window.

Replace—Replaces an object in the queue with a different object. Select an object in the queue to enable the Replace button. Click Replace, and then pick an object in the scene to replace the highlighted item in the queue.

Load/Save Presets Rollout

Create panel > Geometry button > Choose Particle Systems from the drop-down list > Object Type rollout > SuperSpray/Blizzard/PArray/PCloud > Load/Save Presets rollout

Select a SuperSpray/Blizzard/PArray/PCloud emitter. > Modify panel > Load/Save Presets rollout

These options let you store preset values that can be used in other, related particle systems. For example, after setting parameters for a PArray and saving it under a specific name, you can then select another PArray system, and load the preset values into the new system.

Interface

Preset Name—An editable field in which you can define a name for your settings. Click the Save button to save the preset name.

Saved Presets—Contains all the saved preset names. A number of presets are included with 3ds Max; to see what they do, create a particle system, load a preset, and play back the animation. Some of the presets, such as Particle Array’s Shimmer Trail, are most effective with moving particle systems.

Load—Loads the preset currently highlighted in the Saved Presets list. Alternatively, double-click the preset name in the list to load it.

Save—Saves the current name in the Preset Name field and places it in the Saved Presets window.

Delete—Deletes the selected items in the Save Presets window.

Note: Animated parameter values subsequent to frame 0 are not stored.
3ds Max gives you a variety of different ways to create animation, and a wealth of tools for managing and editing animation. See the following links for documentation of some of the animation methods in 3ds Max:

- **Animation Concepts and Methods (page 2–275)** provides information about basic animation with 3ds Max.
- Animation in 3ds Max is accomplished by means of controllers; **Working with Controllers (page 2–289)** gives you an overview of how they work. For specifics about controllers, see **Animation Controllers (page 2–307)**.
- A special type of animation controller is the constraint; for details, see **Animation Constraints (page 2–392)**.
- A powerful method for creating sophisticated, procedural animation is covered in **Wire Parameters (page 2–411)**.
- For animating characters both humanoid and other, as well as complex mechanical assemblies, it’s important to know about **Hierarchies and Kinematics (page 2–416)**.
- **Track View (page 2–501)** gives you access to powerful tools for analyzing and editing animation.
- **Animation Utilities (page 2–653)** can help ease tedious animation tasks.
- When animating a number of different objects the same way, or transferring animation from one object to another, it’s useful to know the information covered in **Saving and Loading Animation (page 3–472)**.
- The **Motion Mixer (page 2–604)** is a powerful tool for combining individual movements into complex animations.
- Another way of combining animation segments is the **Animation Layers (page 2–326)** system.

### Animation Concepts and Methods

With 3ds Max, you can create 3D computer animation for a variety of applications. You can animate characters or vehicles for computer games, or you can animate special effects for film or broadcast. You can create animation for serious purposes such as medical illustration or forensic presentation in the courtroom. Whatever reason you have to animate, you’ll find 3ds Max a capable environment for achieving your goals.
Chapter 12: Animation

The basic way to animate is quite simple. You animate the transform parameters of any object to change its position, rotation, and scale over time. Turning on the Auto Key (page 3–717) button, then moving the time slider places you in a state in which any changes you make will create animation for the selected objects in the viewport.

Animation is used throughout 3ds Max. You can animate the position, rotation, and scale of an object, and almost any parameter setting that affects an object’s shape and surface. You can link objects for hierarchical animation, using both forward and inverse kinematics, and you can edit your animation in Track View (page 2–501).

This section discusses the basics of creating animation. It looks briefly at a comparison between computer animation and classic hand-drawn animation, and then describes the creation of keyframed animation. The following topics are covered here:

- Animation Concepts (page 2–276)
- Using Auto Key Mode (page 2–278)
- Using Set Key Mode (page 2–280)
- Viewing and Copying Transform Keys (page 2–283)
- Controlling Time (page 2–285)
- Setting Time Segments (page 2–286)
- Moving Through Time (page 2–287)
- Choosing a Frame Rate and Playback Speed (page 2–288)

**Animation Concepts**

Animation is based on a principle of human vision. If you view a series of related still images in quick succession, you perceive them as continuous motion. Each individual image is referred to as a frame.

A frame is a single image in an animated film.

**Traditional Animation Method**

Historically, the main difficulty in creating animation has been the effort required of the animator to produce a large number of frames. One minute of animation might require between 720 and 1800 separate images, depending on the quality of the animation. Creating images by hand is a big job. That’s where the technique of keyframing comes in.

Most of the frames in an animation are routine, incremental changes from the previous frame directed toward some goal. Traditional animation studios realized they could increase the productivity of their master artists by having them draw only the important frames, called keyframes. Assistants could then figure out what belonged on the frames in between the keyframes. The in-between frames were called tweens.

Once all of the keyframes and tweens were drawn, the images had to be inked or rendered to produce the final images. Even today, production of a traditional animation usually requires hundreds of artists to generate the thousands of images needed.
The frames marked 1, 2, and 3 are key frames. The other frames are tweens.

The 3ds Max Method

This program is your animation assistant. As the master animator, you create the keyframes that record the beginning and end of each animated sequence. The values at these keyframes are called keys. The software calculates the interpolated values between each key to produce the completed animation.

3ds Max can animate just about any parameter in your scene. You can animate modifier parameters, such as a Bend angle or a Taper amount, material parameters, such as the color or transparency of an object, and much more.

Once you have specified your animation parameters, the renderer takes over the job of shading and rendering each frame. The result is a high-quality animation.

Comparing Frames and Time

Traditional animation methods, and early computer animation programs, are rigidly locked to the concept of producing animation frame by frame. This is okay if you always work in a single format or do not need to specify an animated effect at a precise time.

Unfortunately, animation comes in many formats. Two of the more common formats are film at 24 frames per second (FPS) and NTSC video (page 3–980) at 30 FPS. Also, the need for accurate time-based animation versus frame-based animation is critical as animation becomes more common for scientific and legal presentation.
Different animation formats have differing frame rates.

3ds Max is a time-based animation program. It measures time, and stores your animation values, with an internal precision of 1/4800 of a second. You can configure the program to display time in a format best suited for your work, including traditional frames format. See Time Configuration (page 3–725).

Many of the examples in the following sections describe time using the frames method for the sake of tradition and familiarity. Keep in mind that you are really animating using a very precise time-based method, and frames aren’t created until you instruct the software to render your animation.

Identifying Animation Tools

You can locate the basic animation tools in the following areas of the interface:

**Track View**—Provides detailed animation editing capabilities in several floating or dockable windows. See Track View (page 2–501).

**Track Bar**—Provides quick access to keyframes and interpolation controls. Can be expanded for function curve editing. See Track Bar (page 3–703).

**Motion Panel**—Use this panel to adjust transform controllers that affect all position, rotation, and scale animation. See Working with Controllers (page 2–289).

**Hierarchy Panel**—Use this panel to adjust all parameters governing the linkage of two or more objects. These include inverse kinematics parameters and pivot point adjustments. See Hierarchy Panel (page 3–773).

**Time Controls**—Use these controls to move through time in the viewport displays. You can move to any point in time, and play animations in the viewports. The time controls, documented in Animation and Time Controls (page 3–716), include:

- **Time slider** (page 3–701)
- **Auto Key button** (page 3–717)
- **Set Key buttons** (page 3–718)
- **Animation playback buttons** (page 3–723)
- **Current frame field** (page 3–724)
- **Key Mode toggle** (page 3–724)
- **Time Configuration button** (page 3–725)

To get started with animation, see Using Auto Key Mode (page 2–278).

Using Auto Key Mode

Start creating an animation by turning on the Auto Key button, setting a current time, and then changing something in your scene. You can change the position, rotation, or scale of an object, or change almost any setting or parameter.

When you make a change, a key storing the new value for the changed parameter is created at the current time. If that key was the first animation key created for the parameter, a second animation
Using Auto Key Mode

A key is also created at time 0 to hold the parameter’s original value.

Keys are not created at time 0 until you create at least one key at another time. After that, you can move, delete, and re-create keys at time 0.

Turning Auto Key on has the following effect:

• The Auto Key button, the time slider and the border of the active viewport turn red to indicate you are in animation mode.
• Keys are created whenever you transform an object or change an animatable parameter.
• The time slider sets the time where keys are created.

To begin animating an object:

1. Click Auto Key to turn it on.
2. Drag the time slider to a time other than 0.
3. Do one of the following:
   • Transform an object.
   • Change an animatable parameter.

For example, if you have a cylinder that has not been animated yet, it has no keys. If you turn on Auto Key, and at frame 20 you rotate the cylinder 90 degrees about its Y axis, rotation keys are created at frames 0 and 20. The key at frame 0 stores the original orientation of the cylinder, while the key at frame 20 stores the animated orientation of 90 degrees. When you play the animation, the cylinder rotates 90 degrees about its Y axis over 20 frames.

Modeling Without Animating

Just as you can animate at any time by turning Auto Key on, you can also model at any time in your animation without creating animation keys. The results of changing an object or any other parameters with Auto Key off varies according to whether or not the object or parameters have been animated yet.

• If you create a new object, or change an object parameter that has not been animated yet, you can work at any time with Auto Key off. The changes you make are constant through the entire animation.

For example, you might animate an object bouncing around your scene and then decide to create pads for the object to land on. To do that, you drag the time slider to a time when the bouncing object hits the ground, and make sure Auto Key is off before you proceed. You can then create a pad under the bouncing object and repeat the process at the next time where it hits the ground. Because Auto Key was off, it does not matter at what time the pad objects were created. They remain inanimate through the entire animation.

• If you change an object or parameter that is already animated, while Auto Key is off, the amount of change is applied equally across all the animation keys.

For example, you might animate a sphere’s radius to be 15 at frame 0, 30 at frame 10, and 50 at frame 20. If you drag the time slider to frame 10, turn Auto Key off, and increase the sphere’s radius from 30 to 40, the change in the radius is applied to the other two keys as well. Because you increased the radius by 10 units with Auto Key off, all radius keys are increased by 10 units. The sphere’s radius is now 25 at frame 0, 40 at frame 10, and 60 at frame 20.

If Auto Key had been on when you changed the radius, it would have been an animated change applied only to the key at frame 10.

Identifying What Can Be Animated

Because most parameters in 3ds Max can be animated, the easiest way to find out if something
can be animated is just to try it. Usually, if you want to animate a parameter, it can be animated. Sometimes you need to know in advance if you can animate a parameter. If so, you can use Track View. The Track View Hierarchy list displays every parameter that can be animated. You might also need to add a controller to a track before it can be animated. See Track View (page 2–501) and Animation Controllers (page 2–307).

Using Set Key Mode

The Set Key animation system is designed for the professional character animator who wants to be able to try out poses and then commit those poses to keyframes intentionally. It can also be used by any animator to set keys on specific tracks of objects. This way of working allows more control than the Auto Key method, because it gives you the chance to try out ideas and discard them quickly without having to undo work. It lets you pose your character, and selectively key certain tracks on certain objects through the use of Key Filters and Keyable tracks in Track View.

Note: Although the following information uses the example of animating a character, it also applies to animating a complex mechanical assembly.

Straight-Ahead and Pose-to-Pose

Traditional animation is created one of two ways, either straight-ahead animation or pose-to-pose animation. Straight-ahead animation is drawn starting from the beginning and then additional frames are drawn sequentially thereafter, moving straight ahead in time. Pose-to-pose animation is created by drawing the important frames first, (extremes and breakdowns), and then the intervening frames are filled in later.

Once a character has been correctly drawn for a specific frame, pose-to-pose animation requires that all the keyable tracks needs to be keyframed. This creates a pose of the character that will not be affected if animation for the character is edited at other points in time. If all the animatable tracks are keyed in the extremes, the in-betweening work will not destroy any of those poses.

Set Key and Pose-to-Pose Animation

The number of objects and tracks that require keying for a character, even a simple character, is not something that can be easily handled manually. Set Key makes this process easier by listing all the tracks that are parts of the character that have to be keyed when you want to fix a pose and create a snapshot in time. Keyable tracks let you determine which tracks can be keyed, then Key filters let you work on them selectively, placing keys on only the tracks you want.

Differences Between Set Key and Auto Key Modes

Set Key mode differs from Auto Key in a number of ways.

Auto Key

In Auto Key mode, the workflow is to turn on Auto Key, move to a point in time, then transform objects or change their parameters. All changes register as keyframes. When you turn off Auto Key mode, you no longer are creating keys. Changes made to objects when Auto Key mode is off are applied globally to the animation. This is referred to as Layout mode.

Set Key

In Set Key mode, the workflow is similar, but the behavior is fundamentally different. Turn on Set Key mode, then move to a point in time. Before you transform or change object parameters, you determine the tracks you want to set keys on using Keyable icons in Track View and Filters. Once you know what you plan to key, you try
Using Set Key Mode

out poses in the viewport (transform the objects, change parameters, and so forth).

When you like what you see, click the large Set Keys button or press K on the keyboard to set a key. If you don’t do this, no keys are set.

If you move to another point in time, your changes are lost and have no effect on your animation. For example, if you find that you have a posed character, but at the wrong frame in time, you can hold down Shift and the right-mouse button and drag the time slider to the correct frame without losing your pose.

Using Set Key with Inverse Kinematics

Choosing IK Parameters in Key Filters allows you to use Set Key to keyframe inverse kinematics. This lets you set keys for IK goals and end effectors using Set Key as well as other IK parameters such as Swivel Angle or Twist.

As always, when using Set Key, you can selectively keyframe tracks by combining Keyable icons in Track View with Key Filters.

Set Key doesn’t currently support IK/FK Enabling, so don’t try to keyframe the Enable button using the Set Key button or the keyboard shortcut. Use the Auto Key method when you want to work with IK/FK blending.

Using Set Key with Materials

If you select Materials in Key Filters, you can use Set Key to create keys for materials. Be forewarned that you need to use Keyable Icons to limit the tracks which get keyed. If you simply turn on Materials and set a key, you will place keys on every Material track, something you probably don’t want to have happen.

Using Set Key with Modifiers and Object Parameters

When you want to set a key on an object’s parameters, and you have the Object Parameters Key Filter selected, every parameter will receive a key, unless you have turned off the parameter track in the Controller window of Track View using Keyable icons. It might be easier to simply right-click the parameter spinner to set the key.

Also make sure both Modifiers and Object Parameters are turned on in the Filters dialog (page 2–542) when you are keyframing a modifier gizmo.

Additional Set Key Tools

Additional Set Key Tools are found in the Customize User Interface dialog (page 3–792). On the Keyboard panel, choose Set Key Tools from the Category field. Here, you can set keyboard shortcuts to clear the set key buffer, as well as create keys on just a single axis for a transform.

Using Set Key with Sub-Object Animation

When using Set Key with sub-object animation, you must first assign a controller before creating a key. Sub-objects do not have a default controller assigned upon creation. The controller is assigned by animating at the sub-object level.

Other Methods to Set Keys

You can also set position, rotation, and scale keys by right-clicking the Frame Indicator of the time slider. To set keys on parameters that have spinners, hold down the Shift key and right-click to set a key using the existing parameter value.

Procedures

To use Set Key animation:

1. Turn on the Set Key button.
When the button is red you are now in Set Key mode.
This is a mode where you can try out ideas before you commit to them.

2. Open Track View (either Curve Editor or Dope Sheet).

3. Click the Show Keyable button on the Track View toolbar.

4. Turn off all the other tracks you don’t want to keyframe.
   - The red key means the track will be keyed. If you click the red key, it turns to a gray key, which means that track will not be keyed.
   - Tip: You can toggle multiple tracks as keyable by using the Controller menu > Keyable command.

When you are finished, minimize or close Track View.

5. Click the Key Filters button, and turn on the Filters to choose the tracks you want keyframed.
   - Position, Rotation, and Scale are on by default.
   - You can use the Key Filters button to work on individual tracks selectively. For example, if you are in Track View and the Rotation and Position tracks of a character’s arm are keyable, you can use the key filters to turn off the Position filter and only work on the Rotation tracks.

6. Move the time slider to another point in time, transform your objects or adjust parameters in the command panels to create animation.
   - This does not yet create keyframes.

7. Click the Set Keys button or press [K] on the keyboard to set a key.

When the button turns red, it sets a key which appears on the time ruler. The keys are color coded to reflect which tracks are being keyed.

If you don’t click Set Keys and you move to another point in time, the pose is lost.
   - Tip: To move the pose to another point in time, use the right mouse button to press and drag the time slider. This lets you move to another frame number without losing the pose.

To animate a vertex using set key:
1. Create an editable spline.
2. Select a vertex.
3. Turn on Set Key mode.
4. Move the selected vertex.
5. Click the Set Keys button.

Now a controller has been assigned to the vertex. From this point forward, you can animate.

To set a key on every keyable track of an object:
1. Select the object for which you need to set keys.
2. On the Key Filters dialog, click All.
3. Click the Set Keys button or press [K] on the keyboard.

Spinner Right-Click Menu
To open the spinner right-click menu, right-click the editable field of an animatable parameter.
This menu provides options for cutting, copying, and pasting values, wires, and animation tracks.
between various object parameters. It also allows you to show the parameter in Track View (page 2–501) or in the Parameter Wiring dialog (page 2–412).

**Interface**

With the exceptions of Undo and Select All, each of the following commands takes effect on the parameter you right-click. It’s not necessary to first click in the value field.

<table>
<thead>
<tr>
<th>Command</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>Undo</td>
<td>Reverses the effect of the last action</td>
</tr>
<tr>
<td>Cut</td>
<td>Removes highlighted text to be pasted elsewhere</td>
</tr>
<tr>
<td>Copy</td>
<td>Copies highlighted text to be pasted elsewhere</td>
</tr>
<tr>
<td>Paste</td>
<td>Inserts cut or copied text into the editable field</td>
</tr>
<tr>
<td>Delete</td>
<td>Removes highlighted text</td>
</tr>
<tr>
<td>Select All</td>
<td>Highlights all text within the active editable field</td>
</tr>
<tr>
<td>Copy Animation</td>
<td>Copies the animation controller, including all animation keys, to a buffer, which you can then assign elsewhere by pasting.</td>
</tr>
<tr>
<td>Paste Animation - Copy</td>
<td>Assigns a copy of animation controller in the buffer to the right-clicked field.</td>
</tr>
<tr>
<td>Paste Animation - Instance</td>
<td>Assigns an instance (page 3–957) of the copied animation controller to the right-clicked field.</td>
</tr>
<tr>
<td>Paste Animation - Wire</td>
<td>Opens a Parameter Wiring dialog (page 2–412) with the copied parameter and the paste destination parameter selected. This is equivalent to creating a wire parameter (page 2–411) in the viewport between two parameters.</td>
</tr>
<tr>
<td>Edit Wire</td>
<td>Opens the Parameter Wiring dialog expanded and positioned to show the wire controller assigned to the selected parameter. Note: Edit Wire is available only if a two-way connection is currently applied on the right-clicked parameter.</td>
</tr>
<tr>
<td>Show in Track View</td>
<td>Opens a Track View - Curve Editor window, titled “Selected,” expanded and positioned to show the selected parameter. This is very useful for fast access to a particular curve or track.</td>
</tr>
<tr>
<td>Show in Parameter Wire dialog</td>
<td>Opens a Parameter Wiring dialog expanded and positioned to show the selected parameter.</td>
</tr>
</tbody>
</table>

**Viewing and Copying Transform Keys**

The viewports display white brackets around objects that have transform keys at the current time. These key brackets only appear in viewports using the wireframe shading method.
Use the Track View to view all key types. You can also see all keys for the current selection in the track bar (page 3–703).

For example, suppose you animate a sphere by moving it at frame 20, and scale and rotate it at frame 50. When you drag the time slider, white brackets appear around the sphere at frames 50, 20, and 0, and keys appear at the same frames in the track bar.

If you then apply a modifier such as Bend, and animate its Angle setting at frame 40, you won’t see a white bracket around the sphere at frame 40, but track bar displays a key for the Bend animation.

Controlling Key Bracket Display

You can control the display of key brackets using options in the Preference Settings dialog > Animation panel (page 3–828).

Creating Transform Keys with the Time Slider

You can use the time slider (page 3–701) to create transform keys by copying transform values from one time to another. To specify the type of key to create and the source and destination time for the key values, right-click the time slider to display the Create Key dialog.

You set parameters in the Create Key dialog:

Source Time—Specifies the time from which transform values will be copied.

Destination Time—Specifies the time where the key will be created.

Position, Rotation, Scale—Determine which transform key values will be copied to the destination time.

When you click OK, new keys for the specified transforms are created at the destination time, using values from the source time. Keys do not have to exist at the source frame, because the interpolated values at the frame are used.

You might find it easier to create and manipulate keys with the track bar (page 3–703).

When Auto Key mode is on, you can right-click and drag the time slider at the same time. When you do this, the Source time uses the frame number that you were on when you pressed the mouse button, and the Destination time accepts the frame number that you move the time slider to.

When Set Key mode is on, you can right-click and drag the time slider to move to another frame in time, without losing your character pose. If you find you have posed your character on the wrong frame, simply right-click and drag the time slider, and the pose will be copied to the new frame. Click Set keys to set keys for the pose on the new frame.
Creating Position Lock Keys and Rotation Lock Keys

Creating a lock key creates a key with Linear interpolation. If you create the lock key while an existing key is selected, it changes that key’s interpolation from Smooth to Linear. (Different types of interpolation are described in Bezier Controllers (page 2–310).)

You can create a lock key for position or for rotation.

Lock keys are useful when you want an object to be stationary, but smooth interpolation is causing it to "wobble" on its stationary spot.

To create a lock key:

1. From the Customize menu, choose Customize User Interface.
2. On the Customize User Interface dialog, click the Quads tab, and then, from the drop-down list at the upper right of the dialog, choose Animation.
3. Click the upper left quadrant of the four gray squares that define the quad menus.
   The quad turns yellow.
4. In the Action list to the left, find Create Position Lock Key. Drag it to the window on the right below any menu item. Choose Save and click OK to apply this and close the dialog.
5. (Optional.) Select a key.
6. Alt+right-click the object you’re animating.
   Note: The Auto Key button need not be on.
7. From the quad menu that appears, choose Create Position Lock Key.
   You can also create keyboard shortcuts for these two commands. Create Position Lock Key and Create Rotation Lock Key are main user interface shortcuts. See Keyboard Shortcuts (page 3–871).

Controlling Time

You create animation by changing your scene over time. You can exercise great control over time, as follows:

• How time is measured and displayed.
• The length of the active time segment (the part of the animation in which you’re currently working).
• How much time is covered by each rendered frame of your animation.

Other issues in the topics which follow describe how to move through time and how to view animation in the viewports.

Choosing the Time Display Format

When you start 3ds Max, the default time display is in frames, but you can use alternative time-display formats. For example, you might want to see time in seconds and minutes.

You can specify different time-display formats using the Time Configuration dialog (page 3–725) > Time Display group settings. When you change the time display format, you not only change the way that time is shown in all parts of the software, but you also change the method with which you access time.
You can use these time display formats:

**Frames**—Displays time in whole frames.

This is the default display mode. The amount of time covered by a single frame depends on your choice for the current frame rate. For example, in NTSC video each frame represents 1/30th of a second.

**SMPTE**—Displays time using the Society of Motion Picture and Television Engineers format.

This is the standard time-display format for most professional animation work. From left to right, the SMPTE format displays minutes, seconds, and frames, delineated by colons. For example, 2:16:14 represents 2 minutes, 16 seconds, and 14 frames.

**FRAME:TICKS**—Displays time using frames and the program's internal time increment, called "ticks."

There are 4,800 ticks per second, so you can actually access time intervals as small as 1/4800 of a second.

**MM:SS:TICKS**—Displays time in minutes (MM), seconds (SS), and ticks, delineated by colons.

For example, 2:16:2240 represents 2 minutes, 16 seconds, and 2,240 ticks.

---

### Setting Time Segments

The active time segment specifies a block of working time. You might think of it as a window in time that you use to focus on a specific part of your animation.

#### Specifying an Active Time Segment

You specify the active time segment by setting the Start Time and End Time for the segment on the *Time Configuration dialog* (page 3–725).

You can change the active time segment whenever you want without affecting the keys you've already created. For example, if you have keys scattered over a range of 1000 frames, you can narrow your active time segment to work only on frames 150-300.

Changing the active time segment has the following effect:

- Restricts the range of time you can access using the *time slider* (page 3–701).
- Restricts the range of time displayed when using the animation playback buttons.

The default setting for the active time segment runs from frames 0 to 100, but you can set it to any range.

You can also increase the active time segment using the *track bar* (page 3–703).

#### Rescaling the Active Time Segment

You use the Re-scale Time button on the *Time Configuration dialog* (page 3–725) to change your entire animation based on the active time segment.

Use Re-scale Time as follows:
Moving Through Time

You can move to any time in your active time segment by using either the time slider (page 3–701), or the Current Frame field (page 3–724) in the time controls area. You can also move through time using the playback control buttons.

Using the Time Slider

The time slider shows you the current time, and lets you move to any time in your active time segment.

To change the current time using the time slider, do one of the following:

- Drag the time slider.
- Click in the empty track to either side of the time slider.
- Click the increment arrows at either end of the time slider.

When you click in the slider track, the time slider jumps to the time where you clicked. This is a faster method of moving through time than dragging the time slider.

The time slider displays the current time, followed by a slash (/), followed by the total time in the active time segment. For example 25/100 means frame 25 of 100 frames. The current time also appears in the current time field. If your scene has been animated, it’s played back in all viewports as you drag the time slider.

You can use the < and > keys on the keyboard to advance the time slider a frame at a time. When Key mode is on, this will advance to the next keyframe.

Moving to an Exact Time

The Current Time field always displays the current time. You can also enter a time value and press [Enter] to move to that time.

Using the Time Control Buttons

You use the Time Control buttons to move forward and backward in time and to play your animation in one or more viewports. They work like VCR controls that you use to move through frames and to start and stop animation playback. The Time Control buttons include four buttons for moving...
through time and a center flyout for controlling animation playback:

Go To Start (page 3–722)
Previous Frame/Key (page 3–723)
Play/Stop (page 3–723)
Next Frame/Key (page 3–724)
Go To End (page 3–724)

They work like VCR controls that you use to move through frames and to start and stop animation playback.

### Choosing a Frame Rate and Playback Speed

The frame rate of an animation is expressed in frames per second (FPS). This is the number of frames the software displays and renders for every second of real time.

Because the program stores your animation keys using real time using an internal precision of 1/4800 of a second, you can change the frame rate for your animation at any time without affecting your animation timing.

For example, if you create three seconds of animation using the NTSC video frame rate of 30 FPS, you will have a 90-frame animation. If you later discover you need to output to PAL video, at 25 frames per second, you can switch to that frame rate, and your animation is now set to 75 frames of output. No change in the timing of your animation has occurred. Only the number of frames that 3ds Max will display and render has changed.

### Setting the Frame Rate

You use the settings in the Time Configuration dialog (page 3–725) > Frame Rate group to switch back and forth between frame rates at any time.

- **NTSC**: U.S. and Japanese video standard of about 30 frames per second.
- **PAL**: European video standard of 25 frames per second.
- **Film**: Movie standard of 24 frames per second.
- **Custom**: Frame rate set in the FPS parameter.

### Configuring Animation Playback

You use settings in the Time Configuration dialog (page 3–725) > Playback group to specify the playback speed, and the number of viewports that play the animation.

- **Real Time**: Animation plays at the selected playback speed, skipping frames, if necessary, to maintain the correct speed. Turn this off and the animation will play every frame without trying to maintain the correct speed. The different playback speeds are also useful when using the Motion Capture utility (page 2–655).
- **Active Viewport Only**: Animation plays only in the active viewport. Turn this off and the animation will play in all four viewports at once.
- **Speed**: Choose one of these options to multiply the frame rate by the selected speed.
- **Direction**: When Real Time is off you have the option to change the direction of the animation playback. Choosing Reverse will play the animation from end to start. Choosing Pingpong will play the animation from start to end, and then end to start.
- **Loop**: When Loop is turned off, the animation will play once and stop.

### Viewport Playback Speed

The ability of the program to play your animation at a specified rate depends on many things, including the complexity of the scene, the number of objects moving in the scene, the geometry
display mode, and so on. The worst case is a camera move in shaded mode, in which the viewport is filled with detailed geometry. In such cases, it’s best to simplify the viewport display, using either wireframe display or, in extreme cases, box display mode.

Naturally, it takes more computing power to display your animation in four viewports, and playback smoothness is reduced. When Active Viewport Only is on, you can switch active viewports during playback either by clicking the label of an inactive viewport, or by right-clicking in an inactive viewport.

**Working with Controllers**

Everything you animate in 3ds Max is handled by a controller. A controller is a plug-in that handles the storage and interpolation of all animated values. The default controllers are:

- **Position**: Position XYZ
- **Rotation**: Euler XYZ
- **Scale**: Bezier

Note: New in 3ds Max 9 Extension 1 is the ability to double-click a controller track name on the Motion panel or Track View hierarchy window for fast access to key info or controller parameters. This productivity enhancement can help speed your work when fine-tuning animation.

Although 3ds Max has many different types of controllers, much of the animation is handled by the Bezier controller (page 2–310). Bezier controllers interpolate between keyframes in a smooth curve. You can adjust the key interpolation of these interpolations through the keys on the track bar or in Track View. This is how you can control acceleration, hesitation and other types of motion.

The default controller for Rotation is Euler XYZ, which breaks the rotation down into three individual Bezier Float tracks. The default controller for Position is Position X,Y,Z. The Scale controller default is Bezier.

Note: If you load in files made in earlier versions of the software, their existing controllers will be maintained.

Warning: Be aware that Euler rotations behave differently than TCB rotations. If you are used to using TCB controllers, you can reassign TCB Rotation as the controller and you will get the same behavior you are used to.

3ds Max has a specialized type of controller, called a constraint, that is commonly used to help automate the animation process. A constraint can be used to control an object’s position, rotation, or scale through a binding relationship with another object.

You apply constraints and controllers using commands on the Animation menu. When you assign a controller from this menu, a weighted list controller is automatically applied, with the controller you’ve selected appearing first in the list. The weighted list controller gives you the ability to blend controllers, similar to a nonlinear animation system. If you assign a controller through the Motion panel or Track View, it replaces the existing controller, rather than creating a list controller. You can do that manually if you are working in the Motion panel or Track View.

This section explains techniques for working with controllers. For details about the parameters and use of each controller type, see *Animation Controllers* (page 2–307).

**Understanding Controllers**

Controllers are plug-ins that handle all of the animation tasks in 3ds Max, including:
• Storing animation key values.
• Storing procedural animation settings.
• Interpolating between animation key values.

Most animatable parameters don’t receive a controller until you animate them. As soon as you change an animatable parameter at any frame other than 0 with the Auto Key button on, or click in its track using Curve Editor > Add Keys, a default controller is assigned to the parameter.

Accessing Controllers

There are two places where you work directly with controllers:

• **Track View:** Controllers are indicated in the Hierarchy list by the various controller icons. Each controller has its own individual icon. Using Track View, in either Curve Editor or Dope Sheet mode, you can view and work with the controllers for all objects and all parameters. See Track View (page 2–501).

• **Motion panel:** Contains special tools for working with transform controllers. The Motion panel contains many of the same controller functions as the Curve Editor, plus controls necessary for working with special controllers such as IK Solvers. Using the Motion panel you can view and work with the transform controllers of a single selected object. See Motion Panel (page 3–774).

Categories of Controllers

There are two main categories of controllers. These categories are easy to identify when looking at the Track View - Curve Editor Hierarchy list.

**Single-Parameter Controllers:** Control animation values of a single parameter. Regardless of whether the parameter has a single component, such as the number of sides of a cylinder, or multiple components, such as the RGB values of a color, the controller is handling a single parameter.

**Compound Controllers:** Combine or manage multiple controllers. Compound controllers include high-level Transform controllers, such as **PRS** (page 2–357), the **Euler XYZ Rotation controller** (page 2–318), the **Transform Script controller** (page 2–379), and the **List controller** (page 2–342).

A compound controller appears in the Hierarchy list as a controller icon with subordinate-level branches of other controllers.

Controllers and Constraints

In addition to controllers, the software can animate using constraints. These items are located in the Animation > Constraints menu. The constraints include the following: Attachment, Surface, Path, Link, Position, Orientation, and LookAt.

When you assign a controller in the Motion panel or in Track View, you will see these constraints appearing in the list of available controllers. You can assign them the same as the other controllers, but they are also assignable from the Animation > Constraints submenu. For more information, see Animation Constraints (page 2–392).

Note: If you assign a controller using the Animation > Controller submenu, a list controller is automatically applied to the object, with the selected controller applied beneath the list controller. This is different than controllers that are applied via the Motion panel.

Viewing Controller Types

You can view the controller type assigned to a parameter in both the Curve Editor and in the Motion panel. Before you can view the controller types in Track View, you must do the following:
1. On the Curve Editor toolbar, click the Filters icon. Then in the Filters dialog > Show group, turn on Controller Types.
You can then see the name of the Controller type in the Hierarchy view.

2. Assign controllers to parameters. You can do this on the Assign Controller rollout of the Motion panel, or through the right-click menu in the Hierarchy list in Track View.

The Parameters mode of the Motion panel always displays the transform controller types for the selected object.

### Reading Controller Types

You can tell a lot about how a parameter is animated by looking at the controller type.

**Parameter Name:** Is always visible and is always to the right of the controller icon. It tells you what is animated.

**Interpolation Type:** Usually follows the parameter name. It tells how animation values are calculated. The label Diffuse: Bezier Color indicates a Diffuse color parameter using Bezier interpolation with Color data.

**Data Type:** Usually follows the interpolation type. It tells what type of data is used. The label Height: Linear Float indicates a Height parameter using Linear interpolation with a floating point value.

### Changing Controller Properties

Certain controllers, including procedural ones like Noise (page 2–353), do not use keyframes. For this type of controller, you can analyze and change your animation by editing controller parameters by means of a Properties dialog. The controller type determines whether or not the controller displays a properties dialog and the type of information displayed.

Using Curve Editor you can view controller properties dialogs for multiple tracks simultaneously. The following rules govern viewing multiple controller properties dialogs:

- Each track displays only one properties dialog in each Track View window.
- When properties dialogs for multiple tracks are visible, only one dialog can be active.
- Properties dialogs for tracks that use keys are disabled unless keys are selected.

### Changing Controller Properties

Some controllers do not use keys, using instead a properties dialog that affects the entire animation. Such controllers are usually parametric controllers like Noise, or compound controllers like List.

**To view controller properties in Curve Editor:**

Do one of the following:

- Highlight the label for a parametric or compound controller, right-click the label, and then choose Properties from the shortcut menu to display the properties dialog.

  The dialog title identifies the controller type, the item or object name, and the parameter. For example: Noise Controller:-Box01\Position

- Double-click the label.

You can also view global properties for some transform controllers in the Motion panel. The same controls described above apply.

Controller properties can also be viewed from the track bar (page 3–703). Right-click any key and choose Controller Properties.

### Changing Controller Key Information

Some controllers interpolate between keys that you set on specific frames. Such controllers are always
single parameter controllers such as a Bezier Float controller for Height or TCB for Rotation. These controllers use a Key Info dialog that contains settings for one of more selected keys.

To view key information in the Curve Editor:

- Right-click a key to display the Key Info dialog. If more than one key is highlighted, Key Info displays common information for all of the selected keys. Settings that contain values indicate values common to all of the selected keys. Settings that are blank indicate values that change from key to key.

Viewing key information in the Motion panel always displays the settings for a single transform key.

To view key information for transform controllers in the Motion panel:

1. Select an object.
2. On the Motion panel, click Parameters, if it’s not already active.
3. Click Position, Rotation, or Scale on the Parameters rollout.
   - If the transform controller uses keys, Key Info rollouts appear below the Parameters rollout.

To view key information for transform controllers in the track bar:

1. Select an animated object.
2. Right-click any key in the track bar.
3. From the right-click menu, choose the property to inspect (e.g., Sphere01: X Position), or, if available, choose Controller Properties.

Assigning Controllers

Every parameter has a default controller type that gets assigned the moment the parameter is animated. You can choose from multiple controller types for any parameter and change controllers after the parameter is animated.

Assigning Controllers in Track View

You can assign controllers to any animatable parameter in the Curve Editor by selecting controller items and then choosing Assign Controller on the Controller menu.

You can also assign controllers to any animatable parameter in the Track View — Curve Editor by selecting the parameter in the Hierarchy List then right-clicking and choose Assign Controller from the quad menu.

You can also assign the same controller type to a selection of multiple parameters as long as all the selected parameters can use the same type of controller. For example, you could select the Length, Width, and Height parameters for multiple Box objects and assign the same controller type to all of them. This is because they all use controllers that work on floating point data.

If a parameter has already been animated, then assigning a new controller has one of the following effects:

- The existing animation values are recalculated to produce a similar animation with the new controller. For example, replacing TCB Position with Bezier Position closely preserves the animation.
- The existing animation values are discarded.

Changing Controllers That Do Not Display Properties

Some controller types do not display any properties in Track View or the Motion panel. You change the animation values of these controllers using the Auto Key button in the viewports and using the tools in the Curve Editor Keys and Curves menus, and in the track bar.
Noise Rotation discards the Smooth Rotation animation values.

**Assigning Controllers in the Motion Panel**

You can assign controllers on the Motion panel by selecting an object and then, on the Assign Controller rollout, choosing a controller and clicking the Assign Controller button. You can change the controllers of only one selected object.

**Assigning Controllers Using the Animation Menu**

You can assign controllers using the Animation menu. All the controllers and constraints are available by going to the menu bar and choosing Animation, and then selecting the type of Controller you want and picking the controller from the submenu that displays.

When you assign a controller in this method, a list controller is automatically assigned, and the controller you have selected appears as the first entry in the list. This automatic list controller assignment does not occur if you assign controllers using the Motion panel or Track View. Weighted list controllers allow you to blend between various tracks by animating the weights.

**Tip:** You can use the Animation menu to assign the same type of controller or constraint to several different objects at once. Just select the objects and then choose the controller or constraint from the Animation menu.

**Note:** If an assigned constraint requires designating an additional subject, such as a Path constraint, a rubber-band line extends from the first selected object to the mouse cursor after choosing the constraint. To complete the assignment, position the cursor over a qualifying target object and click.

**Copying and Pasting Controllers**

Right-click any blank area on the Track View toolbars, then choose Show Toolbars > Controllers: Track View. This displays the Controller toolbar with buttons for quick access to controller tools.

Click Copy and Paste on the Track View toolbar to copy and paste controllers. For a general discussion of using Copy and Paste, see *Copying and Pasting Items (page 2–575).*

To copy and paste controllers in the Curve Editor, select the controller track to copy, then right-click and choose Copy from the Track View quad menu. Navigate the Hierarchy list to the target object, select the track, right-click and choose Paste.

**Rules for using Copy and Paste are as follows:**

- You can copy only single controllers. Compound controllers like List or PRS Transform controllers are considered single controllers for Copy and Paste operations.
- You can paste a copied controller into one or more controllers using the same data type.
- You can choose to make an instance or a copy of the pasted controller.
- You can choose to convert other controller instances in the scene automatically.

Clicking Paste displays the Paste dialog, with three controls for determining how the Paste operation is carried out.

**Copy**—Paste the controller as a copy.

**Instance**—Paste the controller as an instance of the source controller. Any change you make to either controller will affect the other.

For example, you can paste a box’s Length controller as an instance into its Height and Width parameters. This makes the box a cube. Changing either of the Length, Width, or Height parameters changes the other two.
Chapter 12: Animation

**Paste Target: Replace All Instances**—When selected, all instances of the target controller receive the paste controller, whether or not they are selected. This keeps all instances of the target controller as instances. When off, the target controller is made unique and the remaining instances are unchanged.

---

**Specifying Default Controllers**

You can specify the permanent defaults for controller types and controller settings to match the way you prefer to work. The following defaults are written to the 3dsmax.ini file:

- The default controller used for each data type
- The default controller settings

---

**Specifying Default Controller Values**

You can specify the default settings for many controller types, or reset controllers to their factory settings on the Preferences dialog.

**To specify default controller settings:**

1. Choose Customize menu > Preferences.
2. In the Preferences dialog > Animation panel > Controller Defaults group, click Set Defaults to display the Set Controller Defaults dialog.
3. From the list of available controllers, choose a controller type and click the Set button to display the default settings supported by the selected controller. For example, with a Bezier controller you can set the In and Out tangents.

**Note:** The default Rotation controller is Euler XYZ, not TCB (Quaternion) as in earlier versions of the software. The default Position controller is now Position XYZ, instead of TCB Position. Only Scale is still Bezier as a default.

Euler XYZ Rotation behaves quite differently from TCB. It gives you three function curves to manipulate, but does not allow rotations of greater than 180 degrees between keys. If you are used to working with TCB controllers, you can change the default rotation controller back to TCB.

Once you click OK, the controller defaults are changed. Changes to the controller default settings are written to your 3dsmax.ini file and become the default for all newly assigned controllers and all new scenes.

You can also revert to the original program defaults for all controllers by clicking Preference Settings dialog > Animation panel > Controller Defaults group > Restore To Factory Settings.
General-Purpose Controllers

The following controllers are general purpose in that you can apply them to parameters of different data types, yet they behave in essentially the same way for those different parameters.

Within certain general-purpose controllers there might be variations according to the data type used by a parameter.

See Animation Controllers (page 2–307) for detailed descriptions of controller properties.

Bezier Controllers

Bezier controllers (page 2–310) interpolate between keys using an adjustable spline curve; they are the default controller for most parameters.

Use Bezier controllers to provide fully adjustable interpolation between keys. Bezier controllers support the following options:

- Adjustable tangent handles.
- Step tangents for abrupt changes from one key to the next.
- Constant velocity control.

You can adjust the key interpolation by choosing among different tangent types in the Key Info dialog.

TCB Controllers

The TCB controller (page 2–377) produces curve-based animation like Bezier controllers. However, TCB controllers use fields to adjust the Tension, Continuity, and Bias of the animation.

Use TCB controllers when you want adjustable, curved interpolation between keys, and you want to use TCB style controls. TCB rotation controllers were the default controller type in versions 4 and earlier.

Linear Controllers

The Linear (page 2–341) controller interpolates between animation keys by evenly dividing the change from one key value to the next by the amount of time between the keys.

Use Linear controllers when you want motion to have a rigid, mechanical look.

Noise Controllers

The Noise (page 2–353) controller produces random, fractal-based animation over a range of frames. Noise controllers are parametric; they do not use keys.

Noise controllers have many possible uses; as in the following examples:

- Use Noise whenever you need completely random animation around a given value. For example, use a Noise Rotation controller when you want an object to wobble in place. A common use for a noise controller is the creation of camera shake.
- Use Noise in a List controller to apply variations to the result of another controller. For example, use a List controller to combine Noise Position with Bezier Position. The Bezier controller moves the object while the Noise controller makes the object shake and stray a little from the trajectory.

XYZ Controllers

The XYZ controllers such as Euler XYZ (page 2–318) and Position XYZ (page 2–356) are specifically designed so that you have three separate curves, one for each axis. This allows you to independently view and control the curves individually. This has advantages over rotation controllers like TCB that do not display function curves at all. XYZ controllers are now the default for rotation animation.
You can adjust the interpolation between keys using the Key Info dialog.

**Audio Controllers**

The Audio controller (page 2–309) converts the amplitude of a recorded sound file or real-time sound wave into values that can be used by an animated parameter.

Use the Audio controller to synchronize parameter values with a sound file. For example, use an Audio controller for a Multiplier Curve to scale a parameter in sync with a sound.

**Special-Purpose Controllers**

The controllers described in this topic are also applied to parameters of different data types, but they are used for special purposes.

**List Controllers**

The List controller (page 2–342) combines multiple controllers into a single effect. It is a compound controller with tools for managing the order in which its internal controllers are calculated. List controllers are weighted, by animating the weights of the different layers you can create an effective non-linear animation system.

Use List controllers to combine controllers as in the following examples:

- Combine Noise Rotation and TCB Rotation controllers to introduce random orbital motion as an object rotates.
- Combine Bezier Position and Path Constraint to make an object follow a path with manually keyframed variation away from the path.

When you apply any controller from the Animation menu, a list controller is automatically placed on the object and the selected controller placed first in the list.

For hands-on experience using weighted list controllers see the bouncing ball exercise in the tutorials.

**Expression/Script Controllers**

You write custom code for Expression controllers (page 2–320) and Script controllers (page 2–372) in an Expression or Script controller dialog. You specify parameters using mathematical expressions, functions, and variables. The code can include values based on the controllers of other objects in the animation.

Note: You can replicate some functions of Expression and Script controllers without having to write code by using parameter wiring or Reaction controllers. See Parameter Wiring Dialog (page 2–412) and Reaction Controllers (page 2–358).

**Motion Capture Controllers**

A Motion Capture controller controls parameters in real time from the input of external devices. Currently supported devices are mouse, keyboard, MIDI device and joystick. Each device has specific properties that must be set:

- After assigning the motion-capture controller, open the controller Properties dialog and bind the type of peripheral device and set device parameters.
- Use the Motion Capture utility (page 2–655) to test and record captured motion.
Explicit Axis Keys

The XYZ controllers assign an individual track to the X, Y, and Z components of the position, rotation, or scale of an object. However, the controllers always assign three keys (one for each axis), by default.

In previous versions of the software, you had to manually edit the keys in order to create explicit axis keys. However, there are now actions available from the Customize User Interface dialog (page 3–792) that let you create explicit keys with the touch of a button.

When an explicit key is created on an axis, any keys on the two remaining axes (at the selected time) will be deleted.

An explicit axis key can only be assigned to objects that already have an XYZ controller assigned to their position, scale, or rotation tracks.

You can also use Keyable Icons to turn on or off tracks for editing. This allows you to set keys on only specified PRS X, Y or Z axes as well. See Keyable Icons (page 2–531).

Interface

Note: These commands are not available in the default user interface. You can use the Customize User Interface dialog to assign a keyboard shortcut to them or add them to your toolbars or menus if you want to use them.

Key Position X, Y, or Z—Creates an explicit key on the designated position axis.

Key Rotation X, Y, or Z—Creates an explicit key on the designated rotation axis.

Key Scale X, Y, or Z—Creates an explicit key on the designated scale axis.

See also

Position XYZ Controller (page 2–356)
General-Purpose Controllers (page 2–295)
Euler XYZ Rotation Controller (page 2–318)
Scale XYZ Controller (page 2–371)

Float Controllers

The following controllers are available only for parameters that use the Float data type.

On/Off Controller

An On/Off controller (page 2–355) controls parameters using binary on and off values. The On/Off track displays a solid blue color in frames that are on, and the background in frames that are off. The on/off state of the parameter switches every time you add a key.

Use for binary parameters such as the Smooth object parameter, or for Visibility tracks.

Boolean Controller

The Boolean Controller is a variation on the On/Off controller. It provides a similar functionality, but with one significant difference. The on/off state of the parameter does not switch automatically every time you add a key. This allows you to effectively add keys in the middle of a sequence without creating unintended drastic changes.

Waveform Controller

A Waveform controller (page 2–381) generates values by combining periodic waveforms. You can specify different types of waveforms and add waveforms together to create complex animation.
Waveform was originally created to control blinking lights. Use it for any value that you want to vary in a regular, oscillating pattern.

**Controlling Transforms**

Transform controllers are compound controllers. They set the type and behavior of the controllers used for Position, Rotation, and Scale.

You assign Transform controllers using either Track View — Curve Editor or the Motion panel. Compound Transform controllers do not display properties in Track View. You can access the parameters of Transform controllers only in the Motion panel.

**Position/Rotation/Scale Controller**

The Position/Rotation/Scale (PRS) controller (page 2–357) is a simple Transform controller applicable for most objects. When applied the PRS Transform controller sets up default Bezier Position, TCB Rotation, and Bezier Scale controllers.

Use a PRS controller whenever you want a standard transform set up or when you want single function curve control over the Position, Rotation, and Scale controllers.

Note: PRS controller is no longer the default controller applied to all objects. The latest version of the software uses Position XYZ and Euler XYZ as the new default controllers for position and rotation transforms.

**Transform Script Controller**

The Transform Script controller (page 2–379) contains all of the information contained in a PRS Controller in one scripted matrix value. Instead of having three separate tracks for position, rotation, and scale, all three values can be simultaneously accessed from one script controller dialog.

Because the transform values are defined by a script, they are easier to animate.

The value of the controller script must be a matrix3 value. A matrix3 value is a 4x3 3D transformation matrix. For more information, see the Matrix3 Values topic in the MAXScript Reference.

**XRef Controller**

The XRef controller (page 2–383) lets you externally reference any type of Transform controller from another scene file. When you assign this controller to your object, it nests the source controller, making it only accessible for playback. You can use the XRef controller either on its own, or combine it with an XRef Object (page 3–394).

**Controlling Position**

Below the Transform controller (page 3–909) is the Position controller. Position is a data type that can use most of the standard controllers such as Bezier, TCB, and Noise.

The controllers described in this topic can be used only as position controllers.

**XYZ Controller**

The XYZ controller breaks a Position controller into three separate Bezier Float controllers. Each of the X, Y, and Z components of position receives its own track.

Use the XYZ controller when you want to have separate key patterns or controller types for each position component.

See Euler XYZ Rotation Controller (page 2–318), Position XYZ Controller (page 2–356), and Scale XYZ Controller (page 2–371).
Controlling Rotation

Below the Transform controller is the Rotation controller. Rotation is a data type that can use most of the standard controllers such as TCB, Linear, and Noise.

Rotations in 3D are very complex. Even the standard controller types behave differently when used for rotation. The most common way of calculating rotations in 3D animation uses four components to define rotation about an arbitrary axis. This is the quaternion method.

The benefits of using quaternion rotation include:

- It produces a direct one-to-one relationship between the quaternion values and how objects interactively rotate in the scene.
- It produces smoother rotation than other methods.

The drawbacks of using quaternion rotation include:

- Rotation values in key information can be difficult to understand.
- Quaternion rotation controllers do not display function curves in Track View — Curve Editor. For this reason Euler XYZ is now the default rotation controller assigned to all objects.

You can use the following controllers only as rotation controllers.

**Smooth Rotation**

Use *Smooth Rotation* (page 2–374) when you want rotation to have a smooth and natural look. Smooth rotation uses nonadjustable curved interpolation, and has the following characteristics:

- You can move keys in Track View to change timing.
- You can directly rotate objects in the viewports to change rotation values.
- You cannot display controller or key properties, or function curves.

**Euler XYZ Rotation**

Use the *Euler XYZ Rotation controller* (page 2–318) when you want individual function curve control for each axis of rotation. Euler XYZ is a compound controller that combines separate, single-value float controllers to specify an angle of rotation about each of the X, Y, and Z axes. Euler XYZ Rotation is the default controller applied to all objects.

Euler XYZ is not as smooth as quaternion rotation, but it is the only rotation type that you can use to edit rotation function curves.

Euler angles are well suited for animating mechanical rotations. They can also be a good choice for an object in an inverse kinematics chain because IK Rotational joints are defined as Euler angles. X, Y, and Z function curves displayed by this controller in Track View represent rotations in “world” or “parent” space which is the rotation system used by most 3D animation packages.

Customers upgrading from earlier versions of the program might find some difficulty in adapting to using Euler XYZ rotation controllers. If you find yourself experiencing unexpected rotation behavior, this might be the reason. Reassign TCB rotation as the default rotation controller and you will be able to regain your customary workflow.

**Controlling Colors**

You can animate colors in 3ds Max just like most other parameters. There are two data types used for controlling colors.
**Point3**: A general-purpose, three-component data type that works with RGB color values. It uses most of the standard controllers.

**Color**: A special data type designed specifically for working with RGB and HSV color values. Color uses the Bezier and RGB controllers.

**Color Point3 Controller**
You can assign any of a variety of Point3 controllers to a material’s color channels, including Point3 Expression, Point3 List, Color RGB (described later in this topic), and so on. When using Point3 controllers for color parameters, an important issue is behavior of the Key Value fields, labeled X, Y, Z. They store color values using only the RGB color model.  
- The X value field stores Red color values.  
- The Y value field stores Green color values.  
- The Z value field stores Blue color values.  
The Point3 Key Value fields do not clamp at the valid color range of 0 to 255. Values that drop below 0 or exceed 255 are ignored by the color parameter but are still displayed in Track View.

**Bezier Color Controller**
The Bezier Color controller (see Bezier Controllers (page 2–310)) is a data type that uses Bezier key interpolation. You can use RGB or HSV color models with the Bezier Color controller.  
The choice of color model is global for all keys used by the controller. You can switch between color models anytime and color key values are correctly converted.  
The Color Value fields are limited to a range of 0 to 255. You can drag the color keys above 255 in Track View Curve Editor, but the values are clamped at 255.

**Color RGB Controller**
Assign a Color RGB controller (page 2–317) to break a Color controller into three separate Bezier Float controllers. Each of the R, G, and B components of color uses its own track.  
Use the Color RGB controller when you want to have separate key patterns or controller types for each color component.

**Morph Controllers**
You can choose from two morph controllers: Cubic and Barycentric; they manage how morph targets blend from one target to another. Morphing can also be achieved by applying a Morpher modifier (page 1–729) to an object.

**Cubic Morph Controller**
A Cubic Morph controller is a TCB-style controller. It uses Tension, Continuity, and Bias controls much like the generic TCB controller.  
The Cubic Morph controller manages only the interpolation from one morph target to the next. If you want to add Morph keys or change the morph target, you must use the Pick Targets and Current Targets rollouts (page 1–314) in the Modify panel.

**Barycentric Morph Controller**
The Barycentric Morph controller (page 2–309) is also a TCB controller like the Cubic Morph controller, except that instead of each key representing a single target, each key represents a series of weights for all targets. A Barycentric Morph key represents a new object which is a blending of all targets.

You can adjust each morph key to percentages of the available morph targets, creating subtle adjustments in the animation.
You can also click Add Keys in Track View to create new Barycentric Morph keys. The added keys contain interpolated values for all targets.

**Motion Panel Commands**

**Trajectories**

Select an object > Motion panel > Trajectories

The Trajectories rollout displays the path an object travels over time. Controls to convert splines into trajectories, trajectories into splines, and to collapse any transform controller into editable keys are also available by choosing Motion panel > Trajectories.

Note: The state of the Trajectory check box under Display in the Object Properties dialog (page 1–117) (and on the Display panel > Display Properties rollout) controls whether trajectories will be visible for an object.

Using trajectories, you can do the following:

- Insert and delete keys from the path.
- Move, rotate, and scale keys on the path.
- Convert the path to a spline object.
- Derive a new path from a spline object.
- Collapse transforms.

Values under Sample Range are used in the Spline Conversion and Collapse Transform functions.

Note: You can now assign the four principal Trajectories functions to keyboard shortcuts and other custom UI items. The following new actions are available via Customize User Interface (page 3–792):

- Trajectory Toggle: If one or more objects are selected, this enters and exits Trajectories mode on the Motion panel.
- Trajectory Key Mode Toggle: Enters and exits the Keys sub-object level for direct editing of animation keys via transformation of the trajectory keys.
- Trajectory Add Key Mode Toggle: Enters and exits Add Key mode.
- Trajectory Add Key Mode Toggle: Enters and exits Delete Key mode.

**Procedures**

To display an object’s trajectory:

1. Select an animated object that moves over time.
2. Right-click the object and choose Properties.
   Trajectory is not available.
3. In the Display Properties group, click By Layer to change this button to By Object. Skip this step if By Object is already displayed.
   Trajectory becomes available.
4. Turn on Trajectory, then click OK.
   The Trajectory is displayed as a red line with white squares and dots. The white squares are keys, the white dots are in-betweens.
To add a key to a trajectory:
1. Select an object.
2. Display the trajectory by following the previous steps.
3. In the Motion panel, click Trajectories.
4. Click Sub-Object to activate Keys and enable editing.
5. Click Add Key.
   The button highlights.
6. Click the trajectory.
   Wherever you click the trajectory a key will be added.
7. Right-click the key and select Key Info from the right-click menu.
   In the Key Info dialog, you can change the In and Out values for the in-betweens on either side of the key. This allows you to use the trajectory key to create the illusion of hesitation or acceleration.
   You can click repeatedly to add many keys in this mode.

To delete a key from a trajectory:
1. Select a key on a trajectory. You can click it, or use window selection.
2. Be sure Add Key is turned off in the Trajectories rollout of the Motion panel.
3. Click Delete Key in the Trajectories rollout of the Motion panel.
   The key is deleted.

To transform keys on a trajectory:
1. Select one or more objects.
2. On the Motion panel, click Trajectories.
3. Click Sub-Object to activate Keys and enable editing.
4. Select one or more keys and use the transform tools on the Main toolbar to move, rotate, or scale the selected keys.

Interface
Sub-Object—Enables key editing. Use the Move, Rotate, and Scale transforms to change the location of a key(s) displayed on a trajectory.

Trajectories rollout
Delete Key—Deletes the selected key(s) from the trajectory.
Add Key—Adds key(s) to the trajectory. This is a modeless tool. When you click this button once, you can then add any number of keys by clicking the trajectory line in the viewport one or more times in succession. To exit Add Key mode, click the button again.

Sample Range group
Start Time/End Time—Specifies the interval for the conversion. If you’re converting from position keyframes to a spline object, this is the time interval for which the trajectory will be sampled. If you’re converting from a spline object to position keys, this is the interval over which the new keys will be placed.
Samples—Sets the number of samples for the conversion. When converting in either direction, the source is sampled at regular intervals, and keys or control points are created on the target object.

Collapse—Collapses the transform of the selected object.

Position, Rotation, Scale—Specifies which transforms you want to collapse.

You must choose at least one check box to activate the Collapse button.

Spline Conversion group

Convert To/Convert From—Converts keyframe position tracks to and from spline objects. This enables you to create a spline trajectory for an object and then convert that spline to keyframes for that object's position track in order to do various keyframe-specific functions (such as applying constant velocity to the keys and normalizing the time). Or, you can convert an object’s position keyframes into a spline object.

Tip: Convert To and Convert From can be used to move an object along a path without using a path constraint.

Collapse Transform group

Generates keys based on the current transformation of the selected object. You can apply this for any type of transform controller assigned to an object, but the main purpose of this function is to “collapse” a parametric transform effect, such as one generated by a Path constraint, into standard, editable keys.

Procedure

To create a PRS transform key:

1. Select an object in the viewports.
2. Drag the time slider to the frame where you want to place a key.
3. On the Motion panel, choose Parameters > PRS Parameters rollout.
4. Click one of the following buttons under Create Key PRS Parameters rollout:
   • Click Position to create a Position key.
   • Click Rotation to create a Rotation key.
   • Click Scale to create a Scale key.

If a particular Position, Rotation, or Scale controller doesn’t use keys, then that button is not available under Create Key. For example, you can’t create Position keys if you’re using a Noise Position controller.
Chapter 12: Animation

Interface

Create Key/Delete Key—Creates or deletes a move, rotate, or scale key at the current frame. These buttons become active or inactive depending on the existence of a key type at the current frame.

For example, if you’re on a frame containing a Scale key, the Scale button is inactive in the Create column because a key already exists. At the same time, the Position and Rotation buttons are inactive in the Delete column because there are no keys of that type to delete.

Position/Rotation/Scale—Determines the contents of the Key Info rollouts that appear below the PRS Parameters rollout on the Motion panel.

Key Info (Basic) Rollout/Dialog

Select an animated object > Motion panel > Parameters > Key Info (Basic) rollout

Select an animated object. > Right-click a key on the track bar. > Choose a controller track.

Curve Editor > Right-click a key.

Parameter Collector (page 1–138) > Click a Properties button.

The Key Info (Basic) rollout or dialog changes the animation value, time, and interpolation methods of one or more selected keys.

The following parameters are available with the Bezier controller, which is the default position controller. The Key Info controls for a TCB position controller are different.

See also

Key Info (Advanced) Rollout/Dialog (page 2–306)

Procedure

To set the tangent type for a key:

1. Select an object and open the Key Info (Basic) rollout.
2. Use the arrows in the upper-left corner of the dialog to select a key.
3. Choose a tangent type from the In or Out tangent flyouts.

Interface

Key number—Shows the current key number. Click the right or left arrows to go to the next or previous key.

Time—Specifies at what time the key occurs.

Time Lock—Prevents horizontal key movement in Track View Edit modes.

Value—Adjusts the position of the selected object at the current key.
Note: In the Key Info dialog for the Bezier Scale controller, a Lock button is displayed beside the X Scale spinner. If you click Lock X, only the X value affects all three axes of scale. The Y and Z values are ignored and their function curves are not displayed. When X is locked, the Y and Z values aren’t affected by changes in the X value. If you click Lock X when all three axes are at identical values, alter the X value, and then unlock X. The Y and Z values remain where they were while X retains its new value.

**Key Tangent Flyouts**—With Bezier controller types, sets the interpolation properties of the In tangent and Out tangent of the key. For details, see Tangent Types (page 2–305).

**Tangent Copy buttons**—Use the arrow buttons at either side of the Key Tangent flyouts to copy the tangent type between the tangents of the current key or between the tangents of the previous and next key.

- The left arrow of the In tangent copies to the Out tangent of the previous key.
- The right arrow of the In tangent copies to the Out tangent of the current key.
- The left arrow of the Out tangent copies to the In tangent of the current key.
- The right arrow of the Out tangent copies to the In tangent of the next key.

**Tangent Types**

You can adjust the tangent type of the Bezier transforms. This means you can adjust the interpolation between keyframes to create particular motion effects. By manipulating tangent types, you can make something hesitate, speed up, slow down, or even stand still. Each key has two tangents: one to define the interpolation before the key, and a second to define interpolation following the key.

Tip: You can also set the default tangent type through the Default In-Out Tangents For New Keys (page 3–721) flyout. By doing so, each new key created with Set Key Mode or Auto Key Mode follows the curve interpolation set by the default tangent type.

- **Smooth**—Creates smooth interpolation through the key.

A linear tangent affects the curve near the key only. Full linear interpolation between two keys occurs only when the Out tangent of the first key and the In tangent of the next key both use a linear tangent.

- **Linear**—Creates linear interpolation at the key.

Choosing Step for the In tangent of the current key also sets the Out tangent of the previous key to Step. Likewise, choosing Step for the Out tangent of the current key also changes the In tangent of the next key to Step.

Using Step tangents, the outgoing value of a key is held constant until the time of the next key is reached. The value then abruptly jumps to the value of the next key. Use this tangent
when you want to animate On/Off switching or instantaneous changes from one value to the next.

**Slow**—Causes the interpolated rate of change to slow down around the key. A slow In tangent decelerates as it approaches the key. A slow Out tangent begins slow and accelerates as it leaves the key.

**Fast**—Causes the interpolated rate of change to speed up around the key. The effect is the opposite of using slow. A fast In tangent accelerates as it approaches the key. A fast Out tangent begins fast and decelerates as it leaves the key.

**Custom**—Displays adjustable tangent handles at the key in Function Curves mode in 3ds Max.

**Flat Tangent**—Displays a smooth interpolation type designed to eliminate overshoot with no editable handles. Tangent slopes automatically take the most direct route to the next key value.

**See also**

*Default In/Out Tangents For New Keys (page 3–721)*

### Key Info (Advanced) Rollout/Dialog

Select an object > Motion panel > Parameters > Key Info (Advanced) rollout

Select an animated object in the viewport. > Right-click a key in track bar. > Choose the name of the controller track such as Sphere01: Z Position. > Key Info dialog > Click Advanced.

Parameter Collector (page 1–138) > Click a Properties button. > Key Info dialog > Click Advanced.

The Key Info (Advanced) rollout or dialog lets you control velocity in three ways:

- You can specify the absolute velocity at a key using the In/Out fields.
- You can average velocity over a time period using Normalize Time.
- With certain controller types, you can force constant velocity from one component key to the next using Constant Velocity.

If you are creating Path animation, you can force constant velocity by placing a Normalize Spline modifier (page 1–747) on the spline used as a path.

**See also**

*Key Info (Basic) Rollout/Dialog (page 2–304)*

### Procedure

**To set normalize time for a key:**

1. Select an object and choose a key to Normalize. You can use the arrows in the Key Info (Basic) rollout to step through Keyframes.

2. In the Key Info (Advanced) rollout, click Normalize Time.

   The key is moved in time to average the velocity through the key.
Interface

- Key Info (Advanced)

<table>
<thead>
<tr>
<th></th>
<th>In:</th>
<th>Out:</th>
</tr>
</thead>
<tbody>
<tr>
<td>X</td>
<td>0.0</td>
<td>0.0</td>

</tr>
</tbody>
</table>

Normalize Time

- Constant Velocity
- Free Handle

In/Out—The In field is the rate of change as the parameter approaches the key. The Out field is the rate of change as the parameter leaves the key.

- These fields are only active for keys using the Custom tangent type.
- The number in the field is the rate of change expressed as parameter units per tick. By changing the two values for X, Y, and Z you are changing the length and angle of the tangent handle.

Lock button—Changes one Custom tangent by changing the other an equal but opposite amount. For example, if you click the Lock button and the In value is 0.85, then the Out value is -0.85.

Normalize Time—Averages the position of the keys in time and applies them to any consecutive blocks of selected keys. Useful if you have an object that speeds up and slows down repeatedly, and you want to smooth out the motion.

Constant Velocity—When on, interpolates values between the key and the next one so that the object moves at a constant velocity across that curve segment. Available only with certain controller types, such as Bezier.

Free Handle—Used for automatically updating the length of the tangent handle. When this is turned off, the length of the tangent is at a fixed percentage from its neighboring key. As you move a key, the handles adjust to stay the same percentage away from the neighboring keys. When this is turned on, the handle lengths are based on time lengths.

Animation Controllers

- Track View > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Choose a controller in the dialog.
- Animation menu > Constraints/Transform Controllers/Position Controllers/Rotation Controllers/Scale Controllers > Choose a controller.

Select an object. > Motion panel > Assign Controller rollout > Select a track. > Assign Controller > Choose a controller in the dialog.

Controllers, like constraints (page 2–392), handle the animation tasks in a scene, including:

- Storing animation key values
- Storing procedural animation settings
- Interpolating between animation key values

An object or parameter doesn’t receive a controller until you animate it. As soon as you change an animatable parameter with Auto Key on, or add a key (page 2–560) in Track View - Dope Sheet (page 2–501), the software assigns a controller to the parameter. The software chooses a default type for the controller, depending on the animation. You can change the default controller to another type.

The animation controllers are organized in the following categories:

- **Float controllers**: for animating floating-point values
Point3 controllers: for animating three-component values such as colors or 3D points
Position controllers: for animating positions of objects and selection sets
Rotation controllers: for animating rotation of objects and selection sets
Scale controllers: for animating the scale of objects and selection sets
Transform controllers: for animating general transforms (position, rotation, and scale) of objects and selection sets

To change an assigned controller, use Controller > Assign (page 2–546) in Track View or in the Motion panel (page 3–774).

The controllers and constraints are:
Attachment Constraint (page 2–393)
Audio Controller (page 2–309)
Bezier Controllers (page 2–310)
Barycentric Morph Controller (page 2–309)
Block Controller (page 2–313)
Boolean Controller (page 2–316)
Color RGB Controller (Point3 XYZ Controller) (page 2–317)
Euler XYZ Rotation Controller (page 2–318)
Expression Controller (page 2–320)
Inverse Kinematics (IK) (page 2–435)
Layer Controller (page 2–325)
Limit Controller (page 2–335)
Linear Controller (page 2–341)
List Controller (page 2–342)
Link Constraint (page 2–403)
LookAt Constraint (page 2–406)
Motion Capture Controller (page 2–347)
Master Point Controller (page 2–346)
Noise Controller (page 2–353)
On/Off Controller (page 2–355)
Orientation Constraint (page 2–409)
Path Constraint (page 2–398)
Position Constraint (page 2–401)
Position XYZ Controller (page 2–356)
PRS Controller (page 2–357)
Reaction Controllers (page 2–358)
Scale XYZ Controller (page 2–371)
Script Controller (page 2–372)
Slave Parameters Dialog (Block Controller) (page 2–391)
Smooth Rotation Controller (page 2–374)
Spring Controller (page 2–375)
Surface Constraint (page 2–396)
TCB Controllers (page 2–377)
Transform Script Controller (page 2–379)
Waveform Controller (page 2–381)

See also
Working with Controllers (page 2–289)
Animation Constraints (page 2–392)
**Audio Controller**

Use the Audio controller to drive the animation of almost any parameter in the software. The Audio controller converts the amplitude of a recorded sound file or real-time sound wave into values that can animate an object or parameter.

With the Audio controller, you have full control over sound channel selection, base threshold, oversampling, and parameter range.

The Audio controller works with most parameters in Track View, including:
- Transforms
- Float values
- Point3 values (color)

**Procedure**

1. Create a box.
2. In the Track View hierarchy, select the Scale track.
3. On the Track View menu, click Controller > Assign, and choose the AudioScale controller.
5. In the Base Scale group, set the Z field to 0.
6. In the Target Scale group, set the Z field to 600.
7. Close the Audio Controller dialog and play the animation.

The box scale is animated along the Z axis.

**Interface**

See Audio Controller Dialog (page 2–386)

---

**Barycentric Morph Controller**

The Barycentric Morph controller is automatically applied when a morph object is created in Create > Geometry > Compound Objects > Morph. Morph targets are selected and keys are created at different times to morph the original object into the shape of the Morph Targets.

**See also**

Morph Compound Object (page 1–314)
Morpher Modifier (page 1–729)

The Barycentric Morph controller represents each key as a series of weights for all targets. One barycentric key represents a new object which is a blending of all targets.

You can adjust each morph key to various percentages of the available morph targets. This lets you create subtle adjustments in the animation.

You can add keys between existing morph keys. The added keys contain interpolated values for all targets.

To access the key properties dialog, select the Morph track, select one of its keys, and click Properties to display the Key Info dialog.

 Procedures

See Morph Compound Object (page 1–314) and Barycentric Morph Controller Key Info Dialog (page 2–388)

Interface

After assigning the Barycentric Morph controller in Create panel > Compound Objects > Morph, then morph parameters for the controller display in the Modify panel and in the Barycentric Controller Key Info dialog, which is displayed by right-clicking over a morph key in Track View — Dope Sheet or the track bar.

See Morph Compound Object (page 1–314) for Morph parameters.

Bezier Controllers

The Bezier controller is the most versatile controller available in the program. Bezier controllers interpolate between keys using an adjustable spline curve. They are the default controller for most parameters.

Use Bezier controllers whenever you want fully adjustable interpolation between keys. Bezier is the only controller that supports the following:

• Dragging tangent handles
• Step tangents for abrupt changes from one key to the next
• Constant velocity controls

 Procedures

To set the tangent type for a key:

1. Select an object that has some animation keys and open the Key Info (Basic) rollout in the Motion panel.
2. Use the arrows to select a key.
3. Choose a tangent type from the In or Out tangent flyouts.

To normalize time for a key:

1. Select an object, and then choose a key to normalize.

You can use the arrows in the Key Info (Basic) rollout to step through keyframes.
2. On the Motion panel, in the Key Info (Advanced) rollout, click Normalize Time. The key is moved in time to average the velocity through the key.

Interface
Motion panel > Parameters > Key Info (Basic) rollout

A Key Info dialog with identical parameters to this rollout is available by right-clicking a key in Track View or the track bar.

- Key Info (Basic)

| Time: | X Value: -59.764 | Y Value: -3.137 | Z Value: 0.0 |

Key number—Shows the current key number. Click the right or left arrows to go to the next or previous key.

Time—Specifies when in time the key occurs.

Time Lock—Controls dragging the key horizontally in Track View edit modes.

X/Y/Z—Adjusts the position of the selected object at the current key.

Key Tangent—Two flyouts set the interpolation properties of the in tangent and out tangent of the key.

Choosing Bezier Tangent Types—Sets the tangent types for one or more keys in the same track using the In and Out tangent flyouts.

See Tangent Types (page 2–305) for detailed information on each of the available tangent choices.

Tangent Copy—Copies the tangent type between the tangents of the current key or between the tangents of the previous and next key. Use the arrow buttons on either side of the Key Tangent flyouts.

The left arrow of the In tangent copies to the Out tangent of the previous key.

The right arrow of the In tangent copies to the Out tangent of the current key.

The left arrow of the Out tangent copies to the In tangent of the current key.

The right arrow of the Out tangent copies to the In tangent of the next key.

Choosing Bezier Tangent Types—Sets the tangent types for one or more keys in the same track using the In and Out tangent flyouts.

Bezier Scale Controller (Lock X)—Causes the X value to affect all three axes of scale. The Y and Z values are ignored and their function curves are not displayed.

When X is locked, the Y and Z values are not affected by changes in the X value. If you lock X when all three axes are at identical values, alter the X value, and then unlock X, the Y and Z values remain where they were while X retains its new value.
Motion panel > Parameters > Key Info (Advanced) rollout

- **Normalize Time**—Averages the position of the keys in time and is applicable to any consecutive blocks of selected keys. Useful if you want to smooth out the motion and have an object that speeds up, slows down, speeds up, and slows down.

- **Constant Velocity**—Interpolates values between a key and the next one in a way that makes the object move at a constant velocity across that curve segment.

- **Free Handle**—Used for automatically updating the length of the tangent handle. When this is turned off, the length of the tangent is at a fixed percentage from its neighboring key. As you move a key, the handles adjust to stay the same percentage away from the neighboring keys. When this is turned on, the handle lengths are based on time lengths.

- **Create Position Lock Key / Create Rotation Lock Key**—Makes the incoming handle of the current key linear, and the outgoing handle of the previous key linear. This is to prevent overshoot from the spline interpolation.

To use these two features, you must first create a keyboard shortcut in Customize > Customize User Interface. Look for Create Position Lock Key and Create Rotation Lock Key in the keyboard shortcut list and assign a key. Or you can also add these commands to the quad menu.

Controls in the rollout affect velocity in three ways:

- Control the absolute velocity at a key using the In/Out values
- Average velocity over a specified amount of time using Normalize Time
- Force constant velocity from one component key to the next using Constant Velocity

**In/Out**—The In field displays the rate of change as the parameter approaches the key. The Out field displays the rate of change as the parameter leaves the key.

These fields are active only for keys using the Custom tangent type.

The number in the field is the rate of change expressed as parameter units per Tick. By changing the two values for X, Y, and Z you are changing the length and angle of the tangent handle.

**Lock button**—When on, changing one Custom tangent changes the other by equal but opposite amount. For example, if the Lock button is on and the In value is 0.85, then the Out value is -0.85.
A Block controller is a global List controller (page 2–342) that allows you to combine several tracks from multiple objects over a range of time, and group them as "Blocks." These Blocks are then used to re-create the animation anywhere in time. Blocks can be added, removed, scaled, moved graphically in Track View, and saved. Blocks can represent either absolute or relative animation.

For example to animate a hand forming a guitar chord, all the rotations of the fingers and hand can be saved as a block. This block can then be used to recreate the hand and finger position, rotation, and animation whenever the chord is played in an animation.

Essentially, block controllers allow you to build up libraries of animations and apply them to objects as you choose.

Tip: Euler Rotations will give you better results than TCB Rotation controllers when you are working with blocks. Block controllers blend clips in a relative repeat manner. If your motions do not loop exactly, your rotations start to drift. Also note that block controllers only work with Keyframe controllers (non-procedural).

**Block Parameters Dialog**

After you create a block by clicking Add in the Master Block Parameters dialog and then selecting tracks in the Track View Pick dialog, clicking OK in the Track View Pick dialog displays the Block Parameters dialog (page 2–389).

**Attach Controls Dialog (Loading Blocks)**

The Attach Controls dialog (page 2–388) is displayed when you click Load in the Master Block Parameters dialog. Tracks in blocks saved previously can be mapped to tracks in the current scene.

**Slave Parameters Dialog (Slave Controller)**

Every time a block is created, all tracks within the block are assigned a slave controller, which allows the MasterBlock to transfer key data. The slave controller tracks appear with the original tracks you used to create the block. See Slave Parameters dialog (page 2–391).
Procedures

Example: To create a block:

1. Animate two objects moving in the viewports. Make the final keyframe for the objects frame 10.
2. Open Track View — Dope Sheet.
3. On the Track View hierarchy, expand Global Tracks, expand Block Control, and then select Available. Available is the track below the Block Control track.
4. From the Track View toolbar, choose Controller menu > Assign, select Master Block in the dialog, and then click OK.
   The Master Block Parameters dialog automatically displays.
5. Click Add on the Master Block Parameters dialog.
6. On the Track View Pick dialog, expand the tracks for the two animated objects.
7. While holding down Ctrl, click the X,Y,Z Position tracks for both objects, and then click OK.
8. On the Block Parameters dialog, type a name in the name field.
   Choose a name that will remind you of the animation in this block.
9. Set the End value to 10, and then click OK.
   The Block will contain animation between frame 0 and frame 10.
10. Click OK to close the Master Block Parameters dialog.
   The block has been created, and you can now use it.
   • Once a block is added, a slave controller is added to the controllers on the original tracks. This enables communication between the track and the Block controller.
   • With the Blend track (below the MasterBlock track in the Track View hierarchy) you can animate how much of the block animation will be in effect. Negative values reverse the animation.
   • Controllers that each block uses are listed under the block name. This allows you to adjust the data for a particular block.

Example continued: To use a block:

1. In the Dope Sheet Key window, right-click the MasterBlock track.
   A pop-up menu displays the name of blocks already created.
2. Select the name of the block you created earlier.
   The Block is displayed in the Key window.
3. Drag the Block to start at frame 20, and click Play.
   The animation repeats at frame 20.
   You can create a number of blocks for different periods of an object’s animation, and use them at different locations in the MasterBlock track.

To move an inserted block:

• In the Key window, select the block and then drag it left or right.

To scale (resize) an inserted block:

• Select the key at the lower left or right corner of the block, and then drag left or right.

To create a copy of a block:

• Hold down Shift and drag the block.
   This creates a new instance of the block, which you can place at a different time.
To remove an inserted block:

- Click to select the block, then press **Delete**.

**Interface**

Inserted blocks appear in the Key window to the right of the MasterBlock controller in the hierarchy under Global Tracks.

**Block Control track**—Displays in Track View under Global Tracks.

To create a MasterBlock Control, expand Block Control, select Available, and choose Controller > Assign.

**MasterBlock Track**—Displays in Track View after you assign a Master Block controller to an available track.

You can right-click the track in the Key window. This displays a pop-up menu that shows the name of blocks that have been created. Choosing a block inserts the block into the MasterBlock track. The dialog also has an entry, Properties, that displays the Master Block Parameters dialog.

In the MasterBlock track, inserted blocks display as colored rectangles. The name of the block appears at the center. In the lower left and right corners are keys that indicate the beginning and end of the block’s animation. Below the name of the block is the letter “R” for relative, or “A” for absolute. Click and drag the center of a block to move it in time. Select a key in the corner of a Block to move one edge of the block (scale time).

Right-click an inserted lock to display the Block Key Properties dialog (described below).

**MasterBlock Subtracks**

Below the main MasterBlock track are subtracks. The first of these is always Blend. The remaining subtracks are initially copies of the tracks used to create the block.

**Blend track**—Lets you animate the influence of the block. You can reduce the block’s influence by creating Blend keys with values less than 1.0. Default=1.0.

**Block-specific subtracks**—Display the block name and its associated tracks. Initially these are copies of the tracks used to create the block. You can edit keys on these tracks to change the block’s behavior.

**Block Key Properties Dialog**

**Relative Motion**—Toggles between relative and absolute motion.

**Start, End**—Set the first and last frames for this instance of the block (this scales the block instance).
Boolean Controller

Main toolbar > Curve Editor (Open) > Select a track containing a float value in the Track View hierarchy > Track View menu bar > Controller menu > Assign > Boolean controller

Graph Editors > Track View – Dope Sheet > Select a track containing a float value in the Track View hierarchy > Track View menu bar > Controller menu > Assign > Boolean controller

The Boolean controller is similar to the On/Off controller (page 2–355). By default, it is assigned to tracks (such as an object’s Visibility track) that provide only binary on and off control.

Note: The Boolean controller is useful for controlling the Enabled state in the History Independent (HI) IK system (page 2–453).

It differs from the On/Off controller in two ways: first, each key has its own float value, either 1.0 or 0.0, signifying its on or off state. This enhancement leads to the second component that differentiates the Boolean controller from its On/Off cousin: the ability to lay down sequential keys without inadvertently changing the on/off state of any keys downstream.

The Boolean controller can be assigned to any parameter that would normally be controlled by a float or boolean class controller, such as sphere’s Hemisphere or Smooth track.

Boolean controller key values can be changed in on of two ways: through Track View’s Dope Sheet editor or through MAXScript.

Note: Although the Boolean controller displays a function curve in Track View’s Curve Editor, it does not display keys. Key time and value must be changed in the Dope Sheet editor.

Procedures

To assign a Boolean controller and add keys:

1. Open Track View’s Dope Sheet editor and select any track that would normally be assigned a float or boolean class controller.

2. Right-click and select Assign Controller. Pick the Boolean controller from the Assign Controller dialog, and click OK.

3. From the main Track View toolbar, select the Add Keys button and click anywhere on the selected track. New keys with a value of 0.0 are added.

To change Boolean controller key values in Track View:

1. Open the Track View Dope Sheet editor and select a track that contains a Boolean controller.

2. Select any key and type 1.0 or 0.0 into the key value field at the bottom of the Track View dialog.

Note: Values greater than 0.0 will automatically be clamped to 1.0
To change Boolean controller key values via MAXScript:

- Enter the following into either the MAXScript Listener or Mini Listener:

  ```maxscript
  node.<animatable_property>.keys[index_integer].value = float
  ```

  where `node` is the object containing the Boolean-controlled parameter (for example, `$Sphere01`, `<animatable_property>` is the parameter itself (for example, `Smooth`, `<index_integer>` is the actual sequential number of the key in the key array, and `<float>` is either 1.0 or 0.0.

### Color RGB Controller (Point3 XYZ Controller)

**Main toolbar > Curve Editor (Open) > Select a material color track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Color RGB**

**Graph Editors > Track View – Curve Editor > Select a material color track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Color RGB**

The Color RGB controller splits the R, G, and B components into three separate tracks. You can use this controller with color tracks. By default, each track is assigned a Bezier Float controller.

The Bezier Float controller is a single parameter controller.

**Note:** The Color RGB and the Point3 XYZ controllers are identical in function, except that the labels of their tracks are RGB and XYZ respectively. Point3 XYZ controllers can be used for functions such as Noise Strength, and the FFD modifier.

### Procedure

**Example: To animate the background color of a rendered animation:**

1. Open Track View – Curve Editor.
2. In the Track View hierarchy, expand the Environment track and then select Background Color.
3. On the Track View menu, click Controller > Assign and select the Color RGB controller.
4. Expand the Background Color track.
5. On the Track View toolbar, click Add Keys.
6. Add three keys along the red track at frames 0, 50, 100.
7. Right-click one of the keys to display the Bezier Float dialog. Change the key values to 0, 400, and 0 respectively.

To see the background color change, move the time slider to the same frame as the key that is being adjusted and render the scene. To see the color change in an animated fashion, you must render the animation.

Although you can set values over 255 in the value field, the actual color value stops at 255.

### Interface

**Bezier Float controller properties.**
Euler XYZ Rotation Controller

Main toolbar > Curve Editor (Open) > Select a rotation track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Euler XYZ

Graph Editors > Track View – Curve Editor > Select a rotation track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Euler XYZ

Select an object in the viewport > Motion Panel > Assign Controller rollout > Select the rotation track. Euler XYZ is assigned as the default controller.

The Euler XYZ Rotation controller is a compound controller that combines separate, single-value float controllers to specify an angle of rotation about each of the X, Y, and Z axes. Euler XYZ is not as smooth as quaternion rotation (used by the TCB Rotation controller), but it is the only rotation type that you can use to edit rotation function curves.

The Euler XYZ Rotation controller assigns an individual track to the X, Y, and Z components of the position, rotation, or scale of an object. However, the controller assigns three keys (one for each axis), by default.

There are actions available from the Customize User Interface dialog (page 3–792) that let you create explicit axis keys.

The Gimbal reference coordinate system (page 1–443) is meant for use with this controller. With other coordinate systems, rotating about one axis always changes at least two tracks. With Gimbal rotation, rotating about one axis changes only one track, making it easier to edit function curves.

Euler versus TCB Rotation

Euler rotation offers several advantages over the TCB Rotation controller, which was the default rotation controller in versions 4 and earlier. Euler rotations provide function curves, while TCB do not. Euler rotations allow for 3 separate curves that can be manipulated in the Curve Editor. TCB rotations can only be controlled using tension continuity and bias settings, making it difficult to keyframe or manipulate X, Y or Z rotations independently.

On the other hand, TCB rotations allow for rotations greater than 180 degrees on a given keyframe. If you turn on the Rotation Windup function, you can get rotation values greater than 360 degrees using TCB.

Tip: Users who are used to working with TCB rotations might find difficulty in adapting to Euler workflow. For these users, it is advised that you reassign TCB as the default rotation controller. See Specifying Default Controllers (page 2–294).

Euler Rotation and the Waveform Float Controller

Because the Euler Rotation controller uses radians, unit adjustments should be made when other controllers are applied to Euler axes. For example, the Waveform Float controller has a default amplitude of 100 in the Characteristic Graph. When the Waveform Float controller is applied to an Euler axis, the default amplitude is 100 radians.
Euler XYZ Rotation Controller

This sets the Amplitude setting to 5729.598 (the number of degrees in 100 radians).

Euler Rotation and the Noise Float Controller

When a Noise Float controller is applied to an Euler axis, the default Strength setting is 286.479 or 50 percent of 10 radians in degrees (maximum deflection).

Euler Rotation and the MIDI Motion Capture Controller

When a MIDI Motion Capture controller is applied, the Parameter Scaling is taken in radians so that the Max. default setting of 1.0 results in an upper boundary of 57.2958 degrees.

Procedures

Example: To use Euler XYZ Rotation:

1. Create a box, and then select the rotation track in Motion panel > Parameters > Assign Controller rollout.
2. Click Assign Controller, and then select Euler XYZ in the Assign Controller dialog list. Click OK.
3. Turn on Auto Key.
4. Select Rotation at the bottom of the PRS Parameters rollout.
5. In the Euler Parameters rollout, select the X axis.
6. In the Create Key group of the PRS Parameters rollout, click Rotation.
   A rotational key is created.
7. Move the time slider to frame 50.
8. Again, in the Create Key group of the PRS Parameters rollout, click Rotation.
9. In the Key Info (Basic) rollout, enter 500 in the value field.
10. Select the Z axis in the Euler Parameters rollout, and then enter 90 in the value field of the Key Info (Basic) rollout.

   Play the animation. The box rotates 500 degrees around the X axis and 90 degrees around the Z axis. In this case the X axis is rotated first, then Z.

To use Euler XYZ with List controllers for local rotation control:

You can mimic the local Euler rotation controller (available in earlier versions of the software) by combining a list controller with an Euler XYZ rotation controller.

1. Select the object for which you want to have local rotational control. For example, create a teapot and a dummy.
2. Animate the dummy.
3. Open the Motion Panel.
4. In the Assign Controller rollout, select the Rotation transform, then assign a LookAt controller to teapot, with the dummy assigned as the LookAt Target.
   You now have an object with rotation controlled through the dummy.
5. With the Rotation: LookAt controller selected in the window, again choose Assign Controller and pick Rotation List.
   Now there is a list controller, with the LookAt Constraint applied as the first rotation controller in the list.
6. Scroll down in the window and select the entry labelled Available, then again click Assign Controller.
7. Choose Euler XYZ.
   You now have a list controller with a LookAt Rotation as the first controller and an Euler XYZ as the second controller.
8. In the Rotation List rollout, highlight Euler XYZ in the Layers window, then click Set Active.

9. In the Euler Parameters rollout, change the Axis Order to ZYX.

Now you can animate the rotation independent of the LookAt rotation control. It should now behave the same as the Local Euler controller that was available in versions 4 and earlier.

### Interface

Euler parameters are displayed in the Motion panel.

The Euler parameters rollout is displayed when Rotation is selected in the PRS Parameters rollout (page 2–357).

- **Axis Order**—Selects the order that rotations are calculated. The default is X,Y,Z order, where the X axis is rotated first.
  - **X**—Displays controller properties for X axis rotation angle.
  - **Y**—Displays controller properties for Y axis rotation angle.
  - **Z**—Displays controller properties for Z axis rotation angle.

Each axis uses its own independent controller using the float data type. For example, the X and Y Rotation axes could use Bezier Float controllers, while the Z rotation axis uses a Noise Float controller.

---

### Expression Controller

**Main toolbar > Curve Editor (Open) > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Expression**

**Interface (page 2–322) Procedures (page 2–321)**

The Expression controller lets you use mathematical expressions to control the following animation aspects:

- Object parameters such as length, width, and height
- Transform and modifier values such as an object’s position coordinates

You can constrain values by basing them on the controller values of other objects in the scene.

An expression is a mathematical function that returns a value. 3ds Max evaluates the expression once for each frame of an animation, generating values that can change from frame to frame.

You can create and manage Expression controllers in Track View (page 2–501) and on the Motion panel (page 3–774). You can assign expressions to the following kinds of scene elements:
### Scene element | Controller
---|---
Creation parameters | Any numeric creation parameter
Transforms | Position [X, Y, Z]
| X Rotation
| Y Rotation
| Z Rotation
| Scale [X%, Y%, Z%]
Modifiers | Any numeric modifier parameter (including creation parameters)
Materials | Colors [R, G, B]
| Any numeric material parameter

Note: Expression controllers can work only with the individual XYZ components of Euler rotation. You can’t assign an expression to TCB Rotation or other kinds of rotation controllers.

### See also
- *Expression Techniques (page 1–146)*
- *Expression Controller Techniques (page 2–324)*
- *Trigonometric Functions (page 1–150)*
- *Vectors (page 1–151)*

### Procedures

#### To assign a constant value to a variable:

1. Highlight the variable name in the Scalars or Vectors list.
2. Click Assign To Constant.

   A new dialog opens.
3. On the dialog, enter the new value (or, in the case of a vector, values) for the constant, and then click OK.

#### To assign a controller to a variable:

1. Highlight the variable name in the Scalars or Vectors list.
2. Click Assign To Controller.

   The Track View Pick subdialog is displayed, showing the track hierarchy. The dialog display is similar to the Track View hierarchy.
3. Highlight the track for the variable to use, and then click OK.

Example: To create an expression that moves a sphere in a precise circle:

1. Create a sphere with Radius=15.0.

You’ll use Track View to create the Expression controller.
2. In the active viewport, right-click the sphere and click Curve Editor.
3. In the Hierarchy list, scroll down to the Objects branch and, if necessary, expand Sphere01 the branch so the sphere’s Position track is visible. Click the Position label to highlight it.
4. In the Hierarchy list, right-click the Position label and then choose Assign Controller

   The Assign Controller dialog opens.
5. Choose Position Expression from the list of controller types, and then click OK.

   The Expression Controller dialog opens.

   Note: You can also open the Expression Controller dialog with Track View > Controller menu > Properties.
6. Replace the default expression by typing the following position expression in the Expression field:

   \[100\cos(360\times NT), 100\sin(360\times NT), 0\]

   The expression specifies a circular path for the sphere. NT is a variable that means normalized time. Movement based on NT happens exactly once per the active time segment, regardless of how many frames are in the animation.
7. Click Evaluate.
8. Play the animation. The sphere moves in a circle about the world origin (0,0,0). The radius of the circular path is 100 units.

Example continued: To change the radius of the circle:

The two 100s in the position expression from the previous procedure specify the radius. To adjust the radius of the circle’s path, create a symbolic variable to represent the radius. The variable has a constant value that is easy to edit.

1. Reopen Track View and the Expression Controller dialog if necessary.
2. In the Name field of the Expression Controller dialog, type radius Make sure Scalar is chosen, and then click Create.
   The variable name "radius" appears in the Scalars list of the dialog.
3. Click Assign To Constant.
   A dialog titled "radius" opens.
4. Enter 150 in the Value field, and then click OK.
   The radius variable is now 150.
5. Next you’ll use the new variable in the expression.

Example continued: To replace the literal value with the variable name:

1. In the Expression field, change 100 to radius in both places. The expression should now look like this:
   \[ \text{radius} \times \cos(360 \times \text{NT}), \text{radius} \times \sin(360 \times \text{NT}), 0 \]
2. Click Evaluate.
3. Play the animation. The sphere moves in a circle about the world origin (0,0,0). The radius of the circular path is 150 units.

Example continued: To make the sphere rotate about a box:

1. Create a box about 40 units square, and animate its position over three or four keyframes.
2. Select the sphere.
3. In the Name field of the Expression Controller dialog, enter boxposn. Choose Vector, and then click Create.
   The name "boxposn" is displayed in the Vectors list in the lower-left area of the dialog.
   Variable names are case sensitive; the variable name should be lower case.
4. Click Assign To Controller.
   The Track View Pick dialog is displayed. It shows the object hierarchy as it appears in the left side of Track View-Dope Sheet.
5. In the Hierarchy list, highlight the Position controller for Box01 and then click OK.
6. In the Expression field, add boxposn as an offset:
   \[ \text{radius} \times \cos(360 \times \text{NT}), \text{radius} \times \sin(360 \times \text{NT}), 0 \] + boxposn.
7. Click Evaluate, and then click Close.
   Play the animation again. The sphere moves in a circle around the box and follows the box wherever it moves.

Interface

![Expression Controller dialog](image)
Tip: You can resize the dialog by dragging an edge or a corner.

Create Variables group
Name—The variable name.
Scalar/Vector—Choose the type of variable to create.
Create—Creates the variable and adds it to the appropriate list.
You must enter a name and specify a type before clicking Create.
Delete—Deletes the highlighted variable in the Scalar or Vector list.
Rename—Renames the highlighted variable in the Scalar or Vector list.

First highlight the variable in the list; this places the name in the Name field. Edit the name in the Name field, and then click Rename; the new name replaces the previous one in the list.

Variable Parameters group
Tick Offset—Contains an offset value.
A tick is 1/4800 of a second. If a variable has a non-zero tick offset, that value is added to the current time.

Expression group
Type an expression in the Expression box.
The expression must be a valid mathematical expression. The result is either a three-value vector for a vector expression (position, scale, or point3) or a scalar value for a float expression.

Description group
Type text in this group to document an expression. For example, you can describe user-defined variables.

Function List—Displays a list of Expression controller functions.
In the list, p, q, and r represent scalar values or scalar expressions; V and W represent vector values or vector expressions.
Save—Saves an expression. Expressions are saved as files with a .xpr file name extension.
Load—Loads an expression.
A saved expression does not include variable definitions or values. After loading the expression, you need to redefine them.

Debug—Displays the Expression Debug window.
This window shows the values of all variables, and the value of the expression. When you change the variables or move the time slider, the Debug window automatically updates so you can interactively view what's happening with the expression. The values for frames (F), normalized time (NT), secs (S), and ticks (T) are also displayed.

Evaluate—Evaluate the expression for each frame in the animation.
There is no explicit assignment (= or := operator) as in a conventional programming language; the assignment is implicit and takes place over time.
If the expression has a syntax error, an error message is displayed. The error message is the first part of the expression itself. The last character in the error message is the point of the error. This is usually where the error actually is, unless the problem is that opening and closing parentheses (or the braces for vectors) don’t match. In this case, evaluation can proceed further before the error is detected.

Close—Closes the Expression Controller dialog.
Expression Controller Techniques

This topic summarizes some useful expression techniques. The following topics review trigonometric functions and vector arithmetic. If you’re familiar with these subjects you can skip the review topics. Use these expressions when you have applied an Expression controller using the Assign Controller rollout in the Motion panel.

Commonly Used Expressions

This topic lists some expressions that you might find useful in situations when you animate.

Circular Path

\[ \text{Radius} \times \cos(360 \times \text{Time}), \]
\[ \text{Radius} \times \sin(360 \times \text{Time}), 0 \]

where \( \text{Time} \) is one of the predefined time variables such as NT or S.

If you make the two \text{Radius} values unequal, you get an elliptical path.

If you specify a nonzero Z component, the path is no longer planar.

Following Another Object

\[ [\text{X}, \text{Y}, \text{Z}] + \text{Position} \]

where \text{Position} is the Position controller of the second object.

The vector \([\text{X}, \text{Y}, \text{Z}]\) can be an offset from the second object. (If it’s \([0,0,0]\), the two objects occupy the same position.) It can also be a vector expression that specifies some movement in itself.

Keeping an Object Between Two Objects

\( (\text{Position1} + \text{Position2}) / 2 \)

where \text{Position1} and \text{Position2} are the Position controllers of two objects.

The divisor 2 constrains the object to be halfway between the two other objects. Other values constrain the object to other locations.

Bouncing Between Other Objects

\( (1+\sin(360 \times \text{Time})) / 2 \times (\text{Pos1} - \text{Pos2}) + \text{Pos2} \)

where \text{Time} is one of the predefined time variables such as NT or S; \text{Pos1} and \text{Pos2} are the Position controllers of two other objects.

The subexpression \((1+\sin(360 \times \text{Time})) / 2\) is a value that oscillates between 0 and 1 over time. \((\text{Pos1} - \text{Pos2})\) is the vector between the two other objects. Multiplying the two and then adding \text{Pos2} as an offset locates the object along this vector.

Changing the Number of an Object’s Segments Based on Camera Distance

This expression varies the number of segments in a cylinder based on the distance of a camera. It is assigned to the cylinder’s Segments creation parameter.

\( \text{if} \{ \text{length(Camera - Myself)} > 35, 3 + (50 \times \text{Height}) / \text{length(Camera - Myself)}, \text{MaxSegs} \} \)

where \text{Camera} is the position controller of the camera; \text{Myself} is the cylinder’s position controller; \text{Height} (= 70) is the cylinder’s height; \text{MaxSegs} (=100) is the maximum number of segments.

When the camera is closer, more segments make the cylinder smoother; when the camera is distant, the smoothing is less important and fewer segments render more quickly.

The \text{if()} function returns its second argument if the first argument is true; otherwise, it returns its third argument. In this example, if the camera is more than 35 units away from the cylinder, the expression calculates the number of segments; if the camera is 35 units away or closer, the number of segments is the \text{MaxSegs} constant.
The values in the second argument are chosen so that as the distance decreases toward the threshold of 35, the number of segments increases toward MaxSegs. The addition “3+” ensures that the cylinder always has at least three segments, even when the division rounds to zero (Segments is an integer).

Note: To the expression, it doesn’t matter whether the camera is moving, or the cylinder, or both.

Layer Controller

Main toolbar > Curve Editor (open) > Highlight a Layer controller track and right-click > Properties

Select layer-enabled object. > Motion Panel > Parameters > Position/Rotation/Scale

The Layer Controller dialog provides commands and options related to the Layer controllers in your scene, which the system automatically assigns for you when you enable animation layers (page 2–326) on an object.

Unlike other controllers, you cannot assign a Layer controller explicitly to a track; you first need to enable layers via the Animation Layers toolbar (page 3–690) or the Controller menu of the Curve Editor.

The Layer controller dialog has similarities to the List controller (page 2–342) dialog. You can refer to it for complementary informations on some of the options.

Animation Layers and Autodesk VIZ

Although the Animation Layers feature is not available in Autodesk VIZ, VIZ can load and save objects that use this feature without any data loss. The Layer controllers continue to exist in VIZ, and can even be viewed and edited in Track View, although editing of the animation-layer data is not recommended if the objects are to be returned to 3ds Max.

Tip: For best results with objects that are to be brought into Autodesk VIZ, collapse any animation layers before saving the objects.

Interface

There are two types of dialogs based on whether you assign a Layer controller to a position or scale track, or to a rotation track.

List Window—Displays all Layer controllers for the selected object, along with their respective weight value.

Set Active—Determines on which layer your animation keys are set. The active controller is marked with an arrow in the list.

Tip: You can also switch between active layers from the drop-down list on the Animation Layers (page 2–326) toolbar.
Delete—Deletes the highlighted controller. A confirmation dialog prompts you before.

Copy—Copies the highlighted controller’s data and enables Paste.

Paste—Puts the copied content onto the highlighted controller.

Weight—Sets the effects of the highlighted Layer controller

Average Weights—When on, the weight values of all the controllers in the list. Available only when you assign a Layer controller to a position track. Default=off.

Pose to Pose—Enables blending among controllers in the list. Available only when you assign a Layer controller to a rotation track. Default=off.

Refer to the List controller (page 2–342) for more information on this option.

Blend Euler As Quat—When on, exposes the rotation axis order for blending the Euler controllers, which can prove useful for controlling gimbal (page 1–443). Available only when you assign a Layer controller to a rotation track. Default=off.

X/Y/Z Order—Sets the order in which the system calculates each rotation axis. Available only when Blend Euler As Quat is on.

Disable—Removes the Layer controller from the select object and reverts the animation keys on the Base Layer to the original controller.

Note: You have to delete or collapse (available on the Animation Layers (page 2–326) toolbar) all layers above the Base Layer before you can disable it.

Animation Layers

Right-click unused area of any toolbar. > Animation Layers

Animation menu > Animation Layers

Animation layers let you combine multiple animation tracks on the same object. You can use layers to store your animation experiments as you try them out, turning them on or off to your liking. To enable, add, and control layers, use commands from the Animation Layers toolbar.

Using animation layers is comparable to using both the List Controller (page 2–342) and biped layer system (page 2–974), while it is more flexible and simpler for the animators to use.

Enabling Animation Layers

When you enable animation layers for a selected object by turning them on in the Enable Anim Layers dialog, 3ds Max assigns a Layer controller (page 2–325) to the animation tracks.

When 3ds Max adds a Layer controller, it copies the original controller into its first layer (called
Animation Layers

Base Layer), preserving any animation data it may already contain.

Note: The Base Layer is not a new layer; it is on the same level as any other controller track.

Note: If you layer-enable a controller but do not see a Layer controller appear in the Track View hierarchy window, open and close the Enable Anim Layers dialog again.

The original controller before you enable animation layers

The Layer controller affects a point 3 branch.

The Layer controller affects a leaf track.

The Layer controller affects a position track.

The new Layer controller nests the List Controller.

The original List controller

To revert from a Layer controller to the original controller, click Disable Anim Layer on the Animation Layers toolbar. However, if your object contains more than one animation layer, you first need to either delete or collapse them before you can disable the Base Layer.

Tip: You can also disable a Layer controller through the Layer Controller dialog (page 2–325).

Note: Turning off a track in the Enable Anim Layers dialog does not disable it.

You can assign a Layer controller either at the leaf level of a controller track (such as a material's Diffuse Color track), or at a branch level (such as a Position track).

The Layer controller affects its Base Layer.

The selected object already has a list controller track when you enable layers, that list controller is preserved within the Base Layer of the new Layer controller.

You can assign a Layer controller either at the leaf level of a controller track (such as a material's
Note: You cannot nest a Layer controller within a List controller or another Layer controller.

**Working with Animation Layers**

The animation layers list works as follows (Refer to the procedure section below (page 2–329) for common workflow examples):

- The list displays all existing layers for the selected object. If the object isn’t layer-enabled, “(Enable Layers)” appears instead.
- By default, the Base Layer is the active layer when you first layer-enable an object. This means that it stores all future animation keys.
- Every subsequent layer you create becomes the new active layer and appears after the previous one in the list.
- When you select an object, its active layer is automatically chosen. When expanded, the drop-down list highlights the active layer.
- When you select multiple objects that have different active layers, “(Multiple Active Layers)” appears.

The drop-down list displays all common layers (that is, with the same name); layers not common to all are unavailable.

- You can turn on or off any layer in the expanded list by clicking its light bulb icon. Turning off a layer hides its animation without deleting it.
- You can include or exclude any layer from the output track by clicking its plus/minus sign icon. The output track contains the sum of all included layers. You can use this track to control other objects’ tracks via MAXScript and parameter wiring.

Tip: For a procedure that demonstrates how to use this option, see Example: To link two objects with wire parameters using the Layer Controller’s output track: (page 2–330).

Each animation layer has a global weight value which, when changed, impacts every controller within that active layer. Similar to the List controller (page 2–342), you can animate a layer’s weight and toggle the visibility of the resulting keys in the Track Bar using the Track Bar Filter menu (page 3–706).
When you add a new animation layer (page 2–334), you can pick a name already in use by an existing layer; this links both layers’ weight track, which is now instanced.

Using Merged or XRef Scenes Containing Layers

When you merge (page 3–463) or externally reference (page 3–407) a source scene (or object) containing layers into your master scene, the system adds the incoming layers to the master scene’s layer list.

Note: All animations within an incoming XRef object or scene is preserved within an XRef controller (page 2–383). You cannot edit them unless you merge the XRef object or XRef controller into your master scene.

If a layer name from the merged or XRef scene matches one from the master scene, both layers become synchronized; that is, the weight track is instanced to both of them.

Collapsing Layers

Collapsing a layer merges keys if any of these conditions are met:

- the two controllers are of similar types (Bezier, Float, TCB, etc.).
- they have the same tangent type.
- the Blend Euler As Quat option of the Layer Controller dialog (page 2–325) is turned off.

However, many factors can cause a collapse per frame (that is, setting a key on every frame):

- If one controller type is TCB (Quaternion) and the other is Bezier (Euler).
- If the Blend Euler As Quat option of the Layer Controller dialog (page 2–325) is turned on, and both rotation controllers are Euler-driven.
- If the Blend Euler As Quat option of the Layer controller is turned off, and both rotation controllers are Euler-driven, but both have different tangent types.
- If either controller is non-keyable.

Procedures: Integrating Animation Layers in a Workflow

The following sequence of procedures illustrate how you can use animation layers in your workflow to quickly create and combine different animation tracks together for the same object. You should be familiar with the basics of animation and key creation before going through the following steps.

Example: To enable layers:

1. Create a teapot, and then turn on Auto Key and set position keys on the X axis at frames 0, 15, and 30.
2. Open the Curve Editor (page 2–507) and locate the teapot’s Position track in the hierarchy window.
3. Choose Animation > Animation Layers to open the Animation Layers toolbar.
4. Make sure the teapot is selected, then click Enable Anim Layers.
5. On the Enable Anim Layers dialog, turn on only the Position track, and click OK.
   The new Layer controller now nests your teapot’s animation.

   **Example: To add a layer and change its controller type:**
   This continues from the previous procedure, in which you enabled layers for an animated object.
   1. Click Add Anim Layer on the Animation Layers toolbar.
   2. On the Create New Animation Layer dialog, enter "Noise Layer" as name, and click OK.
      This adds the new animation layer under the Base Layer in the hierarchy list.
   3. In the hierarchy window of the Curve Editor (page 2–507), Highlight Noise Layer and right-click it.
   4. From the contextual menu, choose Assign Controller and pick a Noise Position controller.
   5. This opens the Noise Controller dialog. Leave the options as they are and close the dialog.
      Two different controllers are now driving the teapot’s position.

Example: To turn a layer on and off:
This procedure discusses turning existing layers on and off. It continues from the previous procedure.

   1. On the Animation Layers toolbar, expand the drop-down list.
      The list currently contains both the original base layer and Noise Layer from the previous procedure.
   2. Move your cursor across the list and click the light bulb icon next to Noise Layer.
      This turns off the layer and hides the Noise controller track from the rest of the tracks.
   3. Drag the time slider and notice how the teapot does not shake anymore.
   4. Try turning on and off both layers in the list to see the results.

   **Example: To link two objects with wire parameters using the Layer Controller’s output track:**
   This procedure refers to a simple way to use the output track to control a cube’s position through wire parameters. It continues from the previous procedure.
   1. Make sure both layers listed on the Animation Layers toolbar are on, as indicated by the light bulb icons.
   2. Create a box next to the teapot.
   3. Right-click it and choose Wire Parameters from the quad menu.
   4. Navigate through the pop-up menu and choose Z Position.
5. A dashed line appears. Click the teapot and choose the X Output Track from the pop-up menu.

6. The Parameter Wiring dialog (page 2–412) opens, with the two highlighted parameters. Click the left directional arrow button to control the cube's position using the teapot's animation.

7. Click Connect and close the window. Drag the time slider and notice how the cube's position in Z matches the teapot's layered animation in X.

8. Select the teapot and expand the layer list from the Animation Layers toolbar.

9. Click the plus sign icon next to the Noise Layer. This excludes the layer from the output track.

10. Drag the time slider again. The cube doesn't move erratically like the teapot.

Try including and excluding both layers in the list to see the results.

**Example: To copy and paste a layer and update an active layer:**

This procedure continues from the previous procedure and focuses solely on the teapot.

1. Make sure the teapot is selected and choose Base Layer from the animation layers list to make it active.

2. Click Copy Anim Layer on the Animation Layers toolbar to buffer this layer and the data it contains.

3. Click Paste New Layer. On the Rename Anim Layer dialog, enter "Changes on Z axis" as name and click OK.

   This new layer becomes the active layer.

4. While Auto Key is on, move the teapot on the Z axis at frames 5 and 20.

   This animation update only affects the position tracks of the active layer.

**Example: To collapse a layer:**

This procedure continues from the previous procedure.

1. In the animation layers list, turn off Noise Layer. Then, choose Changes on Z axis to make it active.
2. Click Collapse Anim Layer on the Animation Layers toolbar. This merges the layer onto the next available one (Base Layer), skipping Noise Layer, which is off.

3. Turn Noise Layer back on in the list.

**Interface**

Enable Anim Layers—Assigns a Layer controller to tracks you specify.

Note: Enabling animation layers does not create a new layer, but rather transfers all chosen controller tracks to the Base Layer.

This opens the Enable Anim Layers dialog, which, similar to the Set Key Filters dialog (page 2–280), lets you turn on tracks you want to assign a Layer controller to.

The Position, Rotation, and Scale tracks are on by default.

Note: Once you turn on a track, you can turn it off only by disabling the respective Layer controller.

If you enable animation layers for an object that has animation loaded in the Motion Mixer (page 2–604), the following dialog opens:

![Enable Anim Layers Dialog](image)

Remapping is necessary in this case because enabling Animation Layers causes the full controller names to change. For example, if a sphere's X position track before enabling Animation Layers is Sphere01\Transform\Position\X Position, then after enabling animation layers it might change to Sphere01\Transform\Position\Base Layer\X Position (the layer name is inserted into the controller name).

If you accept the default dialog option, to create the new map files automatically, 3ds Max automatically generates any necessary XMM files (page 3–478) with the same names as the XAF files and places them in the same directory as the original map files, or if no map files exist, in the same directory as the XAF files. Therefore, when you open this scene file the map file is loaded automatically and no additional mapping is required.

However, if you turn off Automatically Create The New Map Files? before clicking OK, no map files are generated, and the next time you open the scene file you're prompted to create map files. Without map files, the animation doesn't appear correctly.
Select Active Layer Objects—Selects all objects in your scene containing the active layer.

[animation layer list]—Displays all existing layers for the selected object. Each layer in the list contains toggle icons to turn it on or off, as well as include or exclude it from the controller’s output track. See Working with Animation Layers (page 2–328) for more details.

[weight]—Sets a global weight for the active layer, which affects if the active layer is shared by several objects (ex. Base Layer), changing its weight affects them all.

Anim Layer Properties—Opens the Layer Properties dialog (page 3–662), which lets you set global options for layers.

Add Anim Layer—Opens the Create New Animation Layer dialog (page 2–334), which lets you specify settings related to the new layer. This adds a new layer to every track that has a Layer controller.

Delete Anim Layer—Removes the active layer, along with the data it contains. A confirmation dialog prompts you before deletion.

Note: You cannot delete the Base Layer. Alternatively, Click Disable Anim Layer to remove the Layer controller entirely.

Copy Anim Layer—Copies the active layer’s data and enables Paste Active Anim Layer and Paste New Layer.

Paste Active Anim Layer—Overwrites the active layer’s controller type and animation keys with the copied data.

Paste New Layer—Creates a new layer with the copied layer’s controller type and animation keys. Opens the Rename Anim Layer dialog, in which you can use the default layer name or enter your own.

Collapse Anim Layer—Collapses the active layer to the one below it, as long as it is not turned off. If it is, the collapsed layer cycles through the list until it finds an available layer.

Note: Collapsing a layer does not remove the Layer controller. Click Disable Anim Layer to remove it.

Disable Anim Layer—Removes the Layer controller from the selected object. The animation keys on the Base Layer revert to the original controller. A dialog prompts for confirmation.

Note: Before you can disable the Base Layer, you have to delete or collapse all layers above.

Layer Properties Dialog

This dialog provides global options in regards to collapsing animation layers (page 2–326) and isolating the active layer from the rest.
Chapter 12: Animation

Interface

**Collapse To**—Sets the controller type for when you collapse a controller track onto a non-keyable controller track, such as a Noise controller.

- **Bezier or Euler**—On collapse, the resulting track is assigned either a Position XYZ controller (for a Position track), a Bezier Scale controller (for a Scale track), or an Euler XYZ controller (for a Rotation track).

- **Linear or TCB**—On collapse, the resulting track is assigned either a Linear controller (for Position and Scale tracks) or a TCB controller (for a Rotation track).

- **Default**—On collapse, the resulting track is assigned a default controller based on the original controller track. Refer to *Specifying Default Controllers* (page 2–294) for more details.

**Per Frame Collapse Range**—Sets the range to cover when you collapse a layer.

Note: For best results, turn off Collapse to Keys Only, When Possible; otherwise, based on the collapsed layer’s controller and tangent type, the system might collapse to keys instead.

- **Current**—When chosen, a key is set on every frame of your scene’s animation range when you collapse a layer.

- **Range**—When chosen, a key is set on every frame of the animation range you specify.

**Start/End**—Sets the collapse range boundaries.

**Collapse To Keys Only, When Possible**—When you collapse a layer, the keys are merged only when the respective controllers are of the same type, same tangent types, and Blend Eulers As Quats is on. Default=on.

**Mute Layers Above Active Layer**—When on, you see the effects of the layers only up to the active layer, inclusively. This is similar to the Visible Before/After options of the *biped Layers rollout* (page 2–974).

Create New Animation Layer Dialog

Right-click unused area of any toolbar. > Animation Layers > Create New Animation Layer

This dialog lets you choose both the name and controller type of the new layer.

Interface

**Layer Name**—Lists all available layers in your scene. You can use the default name, enter a custom name, or pick one from the list. If you choose an existing layer from the list, it inherits that layer’s name and weight properties. Refer to *Working with Animation Layers* (page 2–328) for more details.

**Tip:** You can rename a layer after it is added from the *Layer Controller dialog* (page 2–325).
Limit Controller

Note: All animation layer names persist in the Layer Name list even after you delete their host object. Resetting the scene clears the list.

[controller type]—Determines the controller type to assign to each track within the animation layer.

• **Duplicate the Active Controller Type**—The new layer’s controller type becomes the same as the one from the active layer, on a per-track basis.
  For example, if a track in the active layer has a Noise controller, adding a new layer copies that controller type.

• **Use Default Controller Type**—When chosen, the new layer’s controller does not take into account the active layer’s controller type and instead uses the original track’s type.

**Limit Controller**

Main toolbar > Curve Editor (Open) > Highlight a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Float Limit

Graph Editors > Track View - Curve Editor > Highlight a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Float Limit

The Limit controller lets you specify upper and lower limits to available controller values, thus restricting the potential value range of the controlled track. For example, in a character rig you could use this to restrict rotation on finger joints so the fingers can’t bend backward. Basically, once a track is limited, and the limit is active, you can’t set a value for the track beyond the limit. You can apply a Limit controller to any other type of controller; the limited controller (that is, the original controller) then appears as a child of the Limit controller in the Track View hierarchy.

Because the Limit controller doesn’t change the original controller, you can easily switch back and forth between the original and the limited animation by toggling the limits. But if you collapse (page 2–522) the Limit controller, the result is the limited animation, and the original animation is no longer available.

Use of the Limit controller makes it faster to set up and create animation. It eliminates the need for expressions or scripts to do the same thing, this improving the ease with which you can set up automation in hierarchies and rigs, creating effects such as avoiding collision, FK joint limits, etc.

For example, a Technical Director might want to assign limits to float values that animators will adjust to make posing easier, enforce standards, or prevent inconsistencies and mistakes. A TD could use limits for:

• light intensity
• finger rotation
• position extents for sliding drawers
• camera field-of-view
• limiting patch resolution to that supported by the game engine

Character riggers can use limits to create complex relationships or shortcuts in rigs. Examples include:

• Wire wrist-twist bones to the rotation of the hand, but limit the rotation of the wrist-twist or hand to stop short of any flipping that might occur.
• Prevent unnatural translation of a spline IK helper by causing limit values for its local position tracks to react to the angle or distance of the helper from surrounding helpers.
• React to when IK is disabled, and match the limits of the solver in FK.
• Limit the position of the IK chain swivel-angle target for the knee so that it can never go behind the character. That is, the target is linked to character’s root.
Use Cases

Following is a brief list of examples of specific uses for the Limit controller:

- Select the Y Rotation tracks of all finger bones in a character’s hands and assign a Limit controller. Use Set Key mode to pose the fingers at the extremes of their ranges of motion and then use the right-click menu (page 2–340) > Set Upper/Lower Limit commands to limit the fingers’ motion.

  Note: Limits are included for Set Key via the Other category.

- You apply a Noise controller to the X Rotation track of a window shutter object to make it rattle, but the object intersects the building at the lower end of its motion range. Apply a Limit controller to the track and set the Lower Limit value to prevent the intersection.

- Following from the previous example, say the wind tears the window shutter from the building at frame 100. If the Noise controller is in a Float List with a Bezier Float, you can weight the noise to 0 at frame 100, when the shutter is torn from the building by the wind, at which point the animator will key the animation. Limits are unnecessary after frame 100. At frame 99, you’d use Set Lower Limit. Then, at frame 100, you’d edit the Lower Limit value to set the limit to much lower, essentially removing the limit. Finally, you would set keyframes to animate its movement past frame 100.

Limitations of the Limit Controller

It’s important to be aware of the following limitations of Limit controllers:

- Limit controllers do not limit IK joints. All IK solvers use their own limits, and ignore Limit controllers. Interactive IK uses the current controllers, but it also has its own limits, so using Limit controllers with interactive IK will produce unpredictable results.

- The Limit controller currently supports only Float controllers. Thus, the Limit controller is currently available only under the name Float Limit.

- Upper and lower limits values are expressed in the same units or coordinates as those used by the limited controller. Thus, for example, Float limits on an X Position track are in local coordinates, not in global coordinates.

Procedure

Example: To use the Limit controller:

1. Start with an animated object, and open Curve Editor.

   In this example, the teapot position was animated on the X axis between extents of about -45 to 40, and on the Y axis between extents of about -80 and 54.

2. Assign the Float Limit controller to a track. In this example, we’ll assign it to the X Position track.

   This opens the Float Limit Controller dialog, where you can set limits and other values, but you might find it easier to do this interactively, so for now just accept the defaults by closing the dialog.

   The track retains its original name (X Position, in this example), but the icon has changed to
indicate that it’s now a Limit controller, and is expandable (see illustration in following step).

3. Expand the track.

The hierarchy contains a child track, named Limited Controller, and a new, expandable child branch named Limits.

4. Click the X Position track and then the Limited Controller track to compare them. Because the original X-axis movement falls within the default limits, the two tracks are identical.

5. Scrub the animation until the X-axis position is where you want to set a limit. In this example, the position is about -20, where we’ll set a lower limit.

6. Highlight the X Position track, and then right-click and from the right-click menu choose Limit Controller > Set Lower Limit.

The graph curve is now clipped below the lower limit. When you scrub the animation, the object doesn’t move beyond that position.

7. Again scrub the animation, stop where you want to set the upper limit, right-click the X Position track, and choose Limit Controller > Set Upper Limit.
In this example, we've set it at about 13. The graph curve is now clipped above the upper limit and below the lower limit. The resulting motion is likewise constrained.

8. Scrub the animation.
   The motion on the X axis is limited at both extremes; wherever the object originally moved beyond the limits, it now behaves as though it's hitting a wall.

9. Again compare the two tracks.
   The Limit Controller (X Position) track clearly shows the upper and lower clipping, while the Limited Controller track shows the original motion.
   The original motion still exists as the Limited Controller track; you can restore it temporarily by toggling the Limit controller.

10. Highlight the X Position track, and then right-click and choose Limit Controller > Toggle Limit.
   Now, when you scrub the animation, the object moves as before.

11. Choose Limit Controller > Toggle Limit again to restore the limits.
   You can copy the Limit controller in two ways: the limits only, or the limits and motion combined. First, you'll copy the limits only.

12. Highlight the Y Position track and note how its curve differs from that of the X Position track.

13. Highlight the X Position track, and then right-click and choose Limit Controller > Copy Limit Only.

14. Highlight the Y Position track, and then right-click and choose Limit Controller > Paste Limit Only. When the Paste dialog opens, click OK to confirm the paste as a copy.
   Now the Y Position track is also limited, using the same extents as the X Position track, but retaining its original underlying motion. To verify this, compare the Y Position track with its child Limited Controller track.
   Next, you'll copy the entire limited X Position track to the Z Position track, including motion and limits. The Z Position track currently is not animated.

15. Highlight the X Position track, and then right-click and choose Copy.

16. Highlight the Z Position track, and then right-click and choose Paste.
   Compare the X and Z Position tracks and both their child Limited Controller tracks. Each corresponding pair of curves is identical. The motion appears as though the object is hitting the inside edge of a box.
   Finally, we'll cover the Smoothing Buffer settings. By default, sharp corners are created wherever a curve is limited, causing abrupt changes in motion. You can smooth off these corners with the Smoothing Buffer parameters, resulting in more natural-looking motion.

17. Highlight the X Position track, and then right-click it and choose Properties.
   This reopens the Float Limit Controller dialog.

18. Use the Upper Limit group > Smoothing Buffer spinner to increase the Smoothing Buffer value as far as it can go.
   As you increase the value, the corners of the upper limit on the graph become smoother.
Note that there's an upper limit to this value; in this case, it's 34.434. This limit is determined by the values of the other three settings on the dialog.

19. Try increasing the Lower Limit group > Smoothing Buffer. It's not possible with the upper smoothing value at its maximum.

20. Decrease the upper smoothing value, and then increase the lower smoothing value.

Now you get smoothing at both the upper and lower limits.

**Interface**

The Limit Controller interface comprises the Float Limit Controller dialog and several-right-click menu items.

The Float Limit Controller dialog opens when you first assign the Limit controller, or when you right-click a highlighted Limit-controller track and choose Properties.

**Enable**—Toggles the Limit controller. When off, the original values of the limited track are in effect. When on, the original values are limited by the Upper Limit and Lower Limit values.

**Upper Limit**

**Enable**—Toggles the upper limit set by the controller. When off, no upper limit is imposed. Default=on.

**[Upper Limit value]**—The highest value permitted by the Limit controller. Any values above this value in the original controller are clipped; that is, they're set to this value, unless smoothing is in effect. Default=1000.0.
You can animate this value via keyframing and other standard methods, and manipulate this animation in Track View via the Upper Limit track in the controller’s Limits branch.

**Smoothing Buffer**—Specifies a smoothing value, so that clipped values at the beginning and end of a clipped range gradually increase and decrease instead of leveling off abruptly.

The maximum total smoothing is determined by the Upper and Lower Limit values. (Upper Limit > Smoothing Buffer value) + (Lower Limit > Smoothing Buffer value) cannot exceed this total. For the smoothest possible results at the upper and lower extents of the clipping, set either Smoothing Buffer value to the maximum amount, and then back it off to half that value and set the other Smoothing Buffer to the same amount.

You can animate the Smoothing Buffer value via keyframing and other standard methods, and manipulate this animation in Track View via the Upper Smoothing track in the controller’s Limits branch.

**Lower Limit Group**

**Enable**—Toggles the lower limit set by the controller. When off, no lower limit is imposed. Default=on.

**[Lower Limit value]**—The lowest value permitted by the Limit controller. Any values below this value in the original controller are clipped; that is, they’re set to this value, unless smoothing is in effect. Default=-1000.0.

You can animate this value via keyframing and other standard methods, and manipulate this animation in Track View via the Lower Limit track in the controller’s Limits branch.

**Smoothing Buffer**—Specifies a smoothing value, so that clipped values at the beginning and end of a clipped range gradually decrease and increase instead of leveling off abruptly.

The maximum total smoothing is determined by the Upper and Lower Limit values. (Upper Limit > Smoothing Buffer value) + (Lower Limit > Smoothing Buffer value) cannot exceed this total. For the smoothest possible results at the upper and lower extents of the clipping, set either Smoothing Buffer value to the maximum amount, and then back it off to half that value and set the other Smoothing Buffer to the same amount.

You can animate the Smoothing Buffer value via keyframing and other standard methods, and manipulate this animation in Track View via the Lower Smoothing track in the controller’s Limits branch.

**Limit Controller right-click menu**

To access the Limit Controller right-click menu, highlight a Limit Controller track in the Track View hierarchy, and then right-click the track and move the cursor to the Controllers quadrant > Limit Controller menu item.

Note: After using Copy Limit Only on a Limit controller track, you can apply a new Limit controller with the same limits to any track by invoking Paste Limit Only.
**Toggle Limit**—Turns the Limit controller on and off. This is the same as the *Enable check box* on the Float Limit Controller dialog.

**Set Upper Limit**—Sets a value/key in the Upper Limit track at the current frame equal to the value at the current frame of the limited track. If there is only one key, the value of the limit is constant over time.

**Set Lower Limit**—Sets a value/key in the Lower Limit track at the current frame equal to the value at the current frame of the limited track. If there is only one key, the value of the limit is constant over time.

**Remove Limit**—Deletes the Limit controller, restoring the original controller without limits.

**Copy Limit Only**—Copies only the Limit values and ignores the limited controller of the highlighted track.

**Paste Limit Only**—Applies only the copied Limit values, or adds a Limit controller with the copied values if one doesn’t exist, while retaining the values of the original limited track.

As with pasting copied controller tracks, you can paste the Limit values as a copy or an instance of the copied Limit controller, with the option to replace all instances of the paste target.

---

**Linear Controller**

<table>
<thead>
<tr>
<th>Main toolbar &gt; Curve Editor (Open) &gt; Select a track in the Track View hierarchy. &gt; Track View menu bar &gt; Controller menu &gt; Assign &gt; Linear</th>
</tr>
</thead>
<tbody>
<tr>
<td>Graph Editors &gt; Track View – Curve Editor &gt; Select a track in the Track View hierarchy. &gt; Track View toolbar &gt; Controller menu &gt; Assign &gt; Linear</td>
</tr>
<tr>
<td>Animation menu &gt; Position, Rotation or Scale controllers &gt; Linear</td>
</tr>
</tbody>
</table>

The Linear controller interpolates between animation keys by evenly dividing the change from one key value to the next by the amount of time between the keys.

Linear controllers do not display a properties dialog. The only information stored in a linear key are the time and animation values.

Use Linear controllers whenever you want a very regular, even transition from one key to the next. For example, use a Linear controller for:

- A color parameter to change from one color to another at a constant rate of change.
- Transforms to produce mechanical, robot-like motion.

**Procedure**

**To assign a Linear controller:**

1. Select an animated object.
2. In the Motion panel > Parameters > Assign Controller rollout, select the Position track in the list window.
3. Click Assign Controller, and then select Linear Position in the Assign Controller dialog.

The animated object has a mechanical motion.
You can also assign this controller in Track View.

**Interface**

No Properties dialog is available for Linear controllers. You can, however, move keys in Track View to change the animation.

**Time**—Change linear key time. Move keys horizontally in Track View Edit Keys or Function Curves mode.

**Value**—Change linear animation values by moving keys vertically in Track View Function Curves mode, change the parameter value in the viewport with Auto Key on.

**List Controller**

You can animate List controller weights to achieve the equivalent of a non-linear animation system. Each list controller track can hold different values from frame to frame that you can turn on or off, or blend between by animating the weights.

**Procedure**

**Example: To use the List controller to combine two controllers:**

1. Create a box, and then turn on Auto Key.
2. Create a simple animation containing three position keys.
3. On the Motion panel > Parameters > Assign Controller rollout, click the position track.
4. Highlight the Position transform and click Assign Controller.
5. Choose the Position List in the Assign Position Controller dialog. Click OK.
6. Click the plus sign in the Position track to expand the track.

When you assign a List controller to a parameter, the current controller is moved one level below the List controller; it becomes the first controller in the list. A second parameter, named Available, is added below the List controller. This is an empty placeholder for the next controller you add to the list.

By default, each listed controller’s Weight setting is set to 100.0. This setting can be changed to increase or decrease the effect the controller has on an object.

When you assign a controller using the Animation menu, a list controller is automatically assigned as a default, with the chosen controller placed first in the list. This behavior differs from when you assign a controller in the Motion Panel or Track View, where only the specified controller is assigned.

You can animate List controller weights to achieve the equivalent of a non-linear animation system. Each list controller track can hold different values from frame to frame that you can turn on or off, or blend between by animating the weights.
7. Click the track named Available and then click the Assign Controller button.

8. Choose Noise Position in the Assign Controller dialog, and then click OK.
   The Noise Controller dialog opens.

9. Play the animation.
   The box follows the original animated path but vibrates randomly.
   Experiment with different Weight settings for each controller and see the results.

Interface
Motion panel > Parameters > List rollout

For example, you have an object using a Position List, with Noise Position and Bezier Position in the list. The Bezier Position controller handles the general motion path of the object, while the Noise Position controller adds a random shake to the motion.

- If Bezier Position is the active controller, you can freely move the object in the scene.
- If Noise Position is the active controller, you cannot move the object because Noise is not an interactive controller.

Delete—Deletes the selected controller.

Cut—Removes the selected controller and stores it in a temporary clipboard. The clipboard contents are only held until you paste the controller, close the List Controller dialog, or exit the Motion panel.

Paste—Puts the contents of the controller clipboard in the position above the selected controller. The clipboard is empty after pasting.

Weight—Exaggerate or minimize the effects of a controller by increasing or decreasing its weight value. Default=100.0.

Average Weights—When on, the weight values of all the controllers in the list are averaged. Available only for the Position List and Scale List controllers. Default=off.

Pose to Pose—Enables blending among controllers in the list. Available only for the Rotation List controller. Default=off.

When off, the List controller weights each rotation individually and adds up the weighted rotations for the final effect. You animate by stacking layers on top of layers, and then weighting in and out their effect. This is the default behavior.

When on, each pose is blended with the results from the previous controllers in the list. This method is not additive, but is instead true pose-to-pose blending. Adjusting the weight of a
controller in the list will blend to and from that pose (controller in list). If the last weight is 100.0, then adjusting the weights of the previous poses in the list won’t have any effect because the last pose has full effect. This is a stack-based approach that is best used for nonlinear animation (NLA) effects. You can paste motion clips or even single-frame poses onto new layers and use the weights to blend the poses together.

**Editable Name Field**—Select one of the controllers in the list window of the Controller list, and then enter a descriptive name in this field. This field lets you rename the controller so it’s easier to identify.

---

**Local Euler XYZ Rotation Controller**

*This controller is no longer available. You can, however, still edit objects that were assigned this controller previously.*

The Local Euler Rotation controller is similar to the *Euler XYZ Rotation controller* (page 2–318), but the angles are with respect to the rotated object’s local coordinate system. With the standard Euler Rotation controller, angles are with respect to parent coordinates. Parameters for this controller are displayed in the Motion panel.

The Local Euler XYZ Rotation controller has three rotation tracks to control rotation on the X, Y, and Z axes. Setting an X axis rotation key will not create keys in the Y and Z tracks on the same frame; each track can be keyed independently. The rotation order of the axes is set in the Motion panel.

**Interface**

The Local Euler parameters are displayed in the Motion panel.

---

**Euler Parameters rollout**

This rollout is displayed when you select Rotation in the *PRS Parameters rollout* (page 2–357).

![](image.png)

**Axis Order**—Sets the order that rotations are calculated in the list. The default is X,Y,Z order, where the X axis is rotated first.

**X**—Displays controller properties for X axis rotation angle.

**Y**—Displays controller properties for Y axis rotation angle.

**Z**—Displays controller properties for Z axis rotation angle.

Each axis uses its own independent controller using the float data type. For example, the X and Y rotation axes could use Bezier Float controllers, while the Z Rotation axis uses a Noise Float controller.

---

**Look At Controller**

Create or select an object that contains a Target component, such as a target spotlight or camera. > Motion panel > Look At Parameters rollout

The Look At controller is automatically assigned as a transform animation controller upon creation of objects that contain targets, including Target Camera, targeted lights (including IES Sun/Sky) and the Tape helper. It cannot be assigned by the user. To assign the equivalent of a Look At controller to an object, use a *LookAt constraint* (page 2–406).

Note: A targeted object’s pitch and heading are adjusted by moving the target, so the only
orientation setting that can be controlled directly by the user is Roll, or bank.

Example: To prevent flipping of targeted objects during rotation:

1. Add a Target Camera object (page 2–1371).
2. Activate the Move tool and use the coordinate display (page 3–708) to position the camera and target at \(0,0,0\) and \(80,0,0\), respectively.
3. Add a Dummy object (page 2–16) and position it at \(0,0,0\).
4. Use Select And Link to link the camera to the dummy, and then link the camera target to the dummy. At this point, the dummy is parent to both the camera and its target.
5. Rotate the dummy about its Y axis, and watch the camera.
   As the target passes through the zenith and nadir of its orbit, the camera flips.
6. Select the camera and go to the Motion panel. On the Look At Parameters rollout, turn on Use Target As Up Node.
7. Again rotate the dummy about its Y axis. The camera no longer flips.

Interface

After you create or select an object that contains a Target component, you can access the object’s Look At properties on the Motion panel. In this rollout you can change the target, create and delete animation keys, set the axis, and adjust other, related parameters.

- **Create Key**—Sets a position, roll (orientation), or scale key at the current frame, depending on which button you click.
- **Delete Key**—Deletes a position, roll (orientation), or scale key at the current frame, depending on which button you click.
- **Pick Target**—Lets you set a target other than the default Target object. Click this button, and then select the new object to use as a target.

Thereafter, the new target controls the object’s orientation. The original target remains in the scene, and can be deleted or used as a Dummy helper.
**Axis**—Specifies the local axis that looks at the target. The Flip check box is used to flip the directions of the axis.

**Use Target as Up Node**—When turned on, the controller forces the object on which it acts (source node) to keep one of its local axes aligned with the look-at direction (the vector between the source node and the target node). It also prevents the source node from rotating around the look-at direction, to avoid flipping about the object's local Z axis.

The flipping behavior is most commonly seen when the line between a targeted object and its target is close to vertical; that is, their positions on the World Z axis are nearly the same.

The option works by aligning one of the source node's local axes with one of the target node's local axes. These axes are picked automatically by the software.

**Note:** This feature lets you properly manipulate Luminaire assemblies. It also provides for trouble-free operation when you *i-drop* (page 3–523) manufacturer luminaire assemblies.

**Tip:** In some cases, the object will flip 90 or 180 degrees even when the Use Target As Up Node option is turned on. This behavior occurs due to the fact that the axis alignment is automatic. To resolve this, apply a roll angle to the object with the coordinate display.

**Position/Roll/Scale**—These three buttons let you specify the other rollouts that appear for this controller. In all three cases, the *Key Info (Basic)* (page 2–304) and *Key Info (Advanced)* (page 2–306) rollouts appear. When Position is active, an additional Position XYZ Parameters rollout lets you specify the position axis.

---

**Master Point Controller**

The Master Point controller is assigned automatically whenever control points, vertices, or vectors (tangent handles) are animated in the sub-object mode of an Editable Spline, Editable Patch, Editable Mesh, Editable Poly, NURBS surface, or FFD. By allowing you to select and move all the sub keys, visually correlate keys to points in the viewports, and change key properties quickly, this controller helps to manage the numerous tracks created when animating vertices, control points, and vectors.

The Master Point controller is displayed as a track with green keys in Track View. Sub tracks below the Master track contain all the animated vertices, control points, and vectors.

**Procedure**

**Example: To animate vertices, viewing the Master Point controller track:**

1. In the Front viewport, create a sphere.
2. Right-click the sphere and select Convert to Editable Mesh in the dialog.
3. On the Editable Mesh > Selection rollout, click Vertex.
5. Turn on Auto Key, and move the time slider to frame 10.
6. In the viewports, select and move some vertices on the sphere.

A key appears on the track bar at frame 10.
7. Right-click the sphere, and select Curve Editor in the dialog.

Track View — Curve Editor is displayed with the sphere at the top of the Controller window.

8. Change modes to Dope Sheet and expand all the sphere tracks in the Track View hierarchy. The Master Point Controller track is displayed, with tracks for the animated vertices below it.

**Interface**

**Master Track Keys**—While in the Track View – Dope Sheet, selecting a master key (green) selects all the sub keys at that frame.

If hundreds of vertices are animated, collapse the master track so that only the master track is visible. Moving the green keys will move all the sub keys.

**Master Track Key Info dialog**

Right-click a green master key in Track View to display the Master Track Key Info dialog (page 2–391).

---

You can control an object’s position, rotation, or other parameters using an external device with the Motion Capture controller.

**Note:** Rotation Motion Capture uses Euler rotations with an X, Y, Z axis order and is subject to the limitations of Euler rotations. See Euler XYZ Rotation Controller (page 2–318).

**The Motion Capture System**

To use motion capture in 3ds Max, you follow these steps:

1. In Track View — Dope Sheet or Motion panel, you assign motion capture animation controllers to the specific tracks you want controlled by external devices.

2. After assigning the motion capture controller, you open the Properties dialog for the track and bind the type of peripheral device(s) that you want. Currently supported devices are mouse, keyboard, MIDI device, and joystick. Each device has specific properties.

3. After binding the devices, adjust their settings and parameters in the lower portion of the Track Properties dialog. These controls vary depending on the type of device.
4. In the Utilities panel, access the Motion Capture utility. You can test and record your motion for any combination of tracks over any range of frames.

5. When you assign a Motion Capture controller, the previously assigned controller is maintained as a child of the Rotation controller. You can continue to adjust the rotation of the object using standard transform controls, while still making motion-capture control available.

**Procedure**

**To use your mouse as an input device to animate the position of a box:**

1. Create a box.

2. In Motion panel > Assign Controller, select the position track for the box in the list window, and then click the Assign Controller.

3. Select Position Motion Capture in the Assign Position Controller dialog, and then click OK.

4. Select X Position in the Motion Capture dialog, select mouse input device, and then click OK.

   **Note:** You can open the Motion Capture dialog by selecting the Position track in the Assign Controller list window, and then right-click and select Properties.

5. In the Mouse Input Device rollout, make sure that horizontal is turned on and Scale is set to 1.

6. In Utilities panel > Motion Capture, click Box01 > Position in the Track list window. Click Start in the Record Controls group.

   Real-time recording is in effect; move the mouse horizontally back and forth. The box moves back and forth along the X axis.

   Play the animation to view the recorded movement.

   By default, a key is generated at every frame.

---

**Interface**

Right-click the transform track in the Track View - Dope Sheet hierarchy to display the Motion Capture Properties dialog.

**Position Motion Capture rollout**

- **Device Bindings:**
  - **X Position:** Joystick X
  - **Y Position:** Horizontal Mouse
  - **Z Position:** MIDI Device

- **Edit Binding:**
  - **Track Name:**

**Mouse Input Device rollout**

- **Mouse Axis:**
  - Horizontal
  - Vertical

- **Scale:** 1.0

- **Flip**
This rollout controls animation using the horizontal or vertical motion of the mouse. The available settings include:

**Horizontal/Vertical**—Specifies which mouse motion drives the animation.

**Scale**—Scales the relative effect of the mouse movement to the animation response. Spinner Value=float, 0 to 999,999

**Flip**—Flips the direction of the response relative to the mouse movement. For example, if moving the mouse horizontally to the right produces a clockwise effect on a Rotation controller, activating Flip will reverse the rotation to counterclockwise.

**Keyboard Input Device rollout**

This rollout lets you assign most keyboard keys to drive the animation.

**Assign**—Click and then press any key. The assigned key is displayed in the list window at right.

**List**—Open the list to select a key.

**Envelope Graph group**

The Envelope Graph group displays a representation of the amplitude curve over time.

**Envelope Parameters group**

These options specify the time the envelope of the action takes effect. This relates to the duration of pressing and releasing the key.

**Attack**—Specifies the time, after pressing the key, for the value to reach its maximum level.

**Decay**—Specifies the time, after having reached maximum, for the value to fall to that specified by the Sustain spinner.

**Sustain**—After the Attack and Decay, specifies the value sustained until you release the key.

**Release**—After releasing the key, specifies the time for the value to fade out to zero.

**Parameter Scaling group**

Provides controls for setting the scale of the envelope and the range of the output value.

**Time**—Specifies the scale of the Attack, Decay, and Release parameters. The value represents the number of seconds for 1 unit. For example, if this value is 1.0, then an Attack value of 1.0 equals 1 second.

**Range**—Sets the maximum output value of the controller.

Note: This controller ignores the state of the Ctrl, Alt, and Shift keys.

**Joystick Input Device rollout**

The Joystick Input Device driver was designed for the Microsoft Sidewinder joystick, which contains more controls than the standard joystick. You can use this device driver for standard joysticks as well.
X, Y, Z—Specifies which joystick direction drives the animation. (Standard joysticks provide X and Y axes only. The Sidewinder provides the Z axis when you twist the joystick.)

Throttle—On the Sidewinder, this is a slider next to the stick.

Scale—Scales the relative effect of the joystick action to the animation response. Spinner Value=float, 0 to 999,999

Flip—Flips the direction of the response.

Accumulate—When off, the joystick position represents an absolute position, and you’re limited to the "rectangle" defined by the limits of the joystick. When the joystick returns to its rest position, the value generated returns to zero. When on, the joystick represents a change in the current position. Moving the joystick forward, for example, can cause an object to start moving, and it will continue to move until you return the joystick to its rest position.

**Joystick Buttons group**

Point-of-View Hat (Left-Right, Up-Down)—A mini joystick on the tip of the main joystick that specifies the direction of the animation.

1, 2, 3, 4—Specifies one of four buttons in the Sidewinder joystick. They work similarly to the Point-of-View Hat, except that each button increases a direction value only while pressed. When you release the button, the value returns to zero (centered).

Inc./Dec.—One of three options that are only available when one of the numbered joystick button options is turned on. This option (Increment/Decrement) means that the value is incremented when the button is down, and decremented when the button is up.

Inc—When on, the value increments when the button is down, and stays at that value when the button is released.

Absolute—When on, the assigned parameters jumps to the value set in the Speed spinner when the button is down, and then jumps back to zero when the button is released. Use this for on/off animations, such as blinking lights.

Speed—Controls the rate at which the value changes when using either the Point-of-View Hat or the four buttons. When using a button option and the Absolute option, this specifies the value that’s output when the button is pressed. Spinner Value=float, -999,999 to 999,999

**Increment Based On Direction group**

This group provides controls that let you derive the direction of movement from a Rotation controller. These options are used primarily when you’re animating a first-person flythrough such as when you’re controlling a camera.
Note: The items in this group are only available when Accumulate is selected in the Joystick Axis group.

**Controller**—Assigns a Rotation Motion Capture controller where the direction will be derived. Typically, this would be the Rotation controller of the camera you’re moving.

**Clear**—Removes the assigned controller.

**Direction X/Y/Z**—Specifies the local axis that will be used as the direction. For a Free Camera, for example, this would be Z, because the camera points in the Z direction. However, if you had a car that pointed along its Y axis, you’d use Y.

**Component X/Y/Z**—Specifies which edit binding to use. Match this to the Edit Binding button in the Device Bindings group. For example, if the Y Edit Binding button is selected, choose the Y Component option.

---

**MIDI Device rollout**

- **MIDI Channel group**
  
  This group contains 16 buttons. You can assign a channel to your MIDI device.

- **MIDI Trigger group**
  
  Here, you define the type of MIDI event (message) that will drive the motion. There are four options; Note, Velocity, Pitch Bend and MIDI controller.

  **Note:** Turn on to let the note number or pitch define the output value. The value is derived from where the note falls within the Note Range, specified in the group below. When the note is at the bottom of the range, the value takes on
the Min value specified in the Parameter Scaling group. When the note is at the top of the range, the value takes on the Max value from the same group. Anything in between is interpolated between the Min and Max values. (Note that Min doesn’t have to be less than Max.) The generated value will slide around as different keys are pressed. The harder a key is pressed, the faster the value changes.

**Speed**— Defines how fast the value changes as keys are pressed.

**Velocity**— Determines the output value based on the velocity that the note pressed. The notes set in the Note Range group specify which notes are valid to press. The value takes on the Min value until a key within the Note Range is pressed. When the key is pressed, the value approaches the Max value based on how hard the key was pressed. (The value actually travels along a parabola toward the Max value.)

**Sustain**— Defines how long it takes the value to move through the parabola.

**Variable**— Sustain duration is scaled by how hard the key is pressed.

**Pitch Bend**— Value is defined by the MIDI instrument’s pitch bend knob. The Note Range doesn’t apply in this case and is not available.

**MIDI Controller**— Specifies a note event when you’re hooked up to a different type of MIDI controller than the typical keyboard. For example, if you’re using a MIDI slider box, you would select the MIDI Controller option, and then use the # spinner to specify the note event for the specify slider.

**Note Range group**

Turn on Note or Velocity, and then set the note range here. A value is derived from where the note falls within the Note Range.

**Low Note**— Set a note and octave for the lower range.

**High Note**— Set a note and octave for the higher range.

See **Note** parameter in the MIDI Trigger group, above.

**Parameter Scaling group**

Contains the Min and Max spinners, which specify the range of generated values. See Note and Velocity above.

**MIDI Channel Viewer**— Displays a dialog that lets you test your MIDI device to see which MIDI channel is receiving events and which notes are being triggered.

**Midi Viewer Dialog**

**MIDI Channel group**

Provides a column of 16 buttons and progress bars representing the 16 MIDI channels. Select the channel where you want to view note activity. The channel progress bars light up when any channel has an event.
MIDI Note group

The 11 Octave buttons let you select which octave you want to view. When a note is played in that octave, a corresponding progress bar lights up in the Note column.

**MIDI Controller**—When using a different type of MIDI controller, such as a slider box, you can specify a note event, and then watch the corresponding progress bar light up when you activate that event. (You can find the correct note number by activating the event while watching the Note Number field in the group below.)

**Channel**—Displays the currently selected channel. This is one of four text fields that display all of the values being generated by the MIDI device as you activate an event.

**Event**—Displays the type of MIDI event being sent. For example:
- Note On: 9
- Note Off: 8
- Pitch Bend: 14
- MIDI Controller: 11

**Velocity**—Displays the velocity, which has a different meaning depending on the event. For the most common event, a note being pressed, this value represents the velocity at which the key was struck. Other events, however, might generate a continuous value. For example, a pitch bend event transmits the position of the pitch bend.

**Note Number**—Displays the corresponding note number for the event. When you’re using a non keyboard MIDI device, such as a slider box, you can use this to identify the note number of a specific slider.

---

### Noise Controller

Main toolbar > Curve Editor (Open) > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Noise

Graph Editors > Track View – Curve Editor > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Noise

The Noise controller produces random, fractal-based animation over a range of frames. Noise controllers are parametric; they work on a range of frames, but do not use keys.

When you assign a Noise controller in Track View or the Motion panel, it is initially applied to all frames in the current time segment. You can change the range of frames by dragging the Noise range bar in Track View.

- Use Noise whenever you need completely random animation around a given value. For example, use a Noise Rotation controller when you want an object to wobble in place.
- Use Noise as part of a compound List controller to apply noise variations to the result of another controller. For example, use a List controller to combine Noise Position with Bezier Position.

The Bezier controller moves the object through your scene while the Noise controller makes the object shake and stray a little from the path.

**Procedure**

**Example: To apply a Noise controller to a rotation track:**

1. Create a box in any viewport.
2. In the Motion panel > Parameters > Assign Controller rollout, select the rotation track in the list window.

3. Click Assign Controller.

4. Select Noise rotation from the list of controllers.
   The Noise Controller dialog automatically opens.

5. Play the animation.
   The box rotates randomly around all three axes.
Because the non-modal Noise Controller dialog is still open, you can adjust parameters and see the results in real time.

## Interface

**Characteristic Graph**—Shows a stylized graph of how changing Noise properties affects the Noise curve.

**Seed**—Starts the noise calculations. Changing the seed creates a new curve.

**Frequency**—Controls the peaks and valleys of the noise curve. The useful range is from 0.01 to 1.0. High values create jagged, heavily oscillating noise curves. Low values create soft, gentle noise curves.

**Strength fields**—Sets the value range for noise output. These values can be animated.

The number and meaning of the fields vary with different parameter data types. Some typical field arrangements are:
- XYZ fields for Position and Point3 keys
- XYZ percentage fields for Scale keys
- A single value field for Float keys

**>0 Value constraint**—Forces Noise values to stay positive. Each strength field has its own >0 constraint.

When on, the application of the Strength field is changed. Noise values will range from 0 to the value of Strength; most values will hover around Strength/2.

**Ramp In**—Sets the amount of time Noise takes to build to its full strength. A value of 0 causes Noise to start immediately at full strength at the start of its range. Any other value causes Noise to start at 0 strength and then build to full strength by the elapsed time set in the Ramp In field.

**Ramp Out**—Sets the amount of time Noise takes to fall to 0 strength. A value of 0 causes Noise to stop immediately at the end of its range. Any other value causes Noise to fall off to 0 strength by the end of its range. The value in the Ramp Out field sets the amount of time before the end of the range that Noise begins to fall off.

**Fractal Noise**—Generates noise using a fractal Brownian motion. The main value of using Fractal Noise is that it activates the Roughness field.

**Roughness**—Changes the roughness of the Noise curve (when Fractal Noise is turned on). Where Frequency sets the smoothness of the overall Noise effect, Roughness changes the smoothness of the Noise curve itself.
On/Off Controller

The On/Off controller provides binary on and off control. It is similar to the Boolean controller (page 2–316). For example, you can apply an On/Off controller to the Visibility track of an object.

You can view the curve for this controller in the Function Curve display, but it's not editable. In addition, there's no Properties dialog for this controller.

Note: When you load a scene from version 1.x of the software that contains a Visibility controller, the controller is automatically converted to an On/Off controller.

See also

Boolean Controller (page 2–316)

Procedure

Example: To use the On/Off controller to control an object’s visibility:

1. Create a cylinder, and open Track View.
2. In Track View, select the Cylinder track and click Tracks > Visibility Track > Add.

A Visibility and Transform track are now added.
3. Select the track named Visibility.
4. From the Track View toolbar > Controller menu > Assign and select On/Off in the Assign Controller dialog. Click OK.

If you change modes to Dope Sheet, note that the entire track region is filled by a blue bar.
5. Click the Add Keys button in Track View — Dope Sheet and add a key at frame 20.

The blue bar stops at frame 20.
6. Add another key at frame 60.

The track is now blue again following frame 60.
7. Add some additional keys in the Visibility Track. Each added key reverses the on/off blue pattern following the added key.

Tip: You can select two or more keys and copy them to different positions. This allows you to create even intervals for the On/Off effect.

Interface

You assign the On/Off Controller in Track View.

The On/Off track displays a solid blue color in frames that are On, and no blue in frames that are Off. When you add a key to an On section of the track, the section following that key is turned off. When you add a key to an Off section, the following section is turned on and colored blue.
Chapter 12: Animation

Position XYZ Controller

Main toolbar > Curve Editor (Open) > Select a position track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Position XYZ

The Position XYZ controller splits the X, Y, and Z components into three separate tracks (similarly to the Euler XYZ Rotation controller (page 2–318)). This provides separate control of the three tracks when referenced from Expression controllers.

The Position XYZ controller assigns three keys (one for each axis), by default.

In earlier versions of 3ds Max, you had to edit the keys manually in order to create explicit axis keys. However, there are now actions available from the Customize User Interface dialog (page 3–792) that let you create explicit axis keys using Set Key Mode (page 2–280).

Procedure

Example: To use the Position XYZ and Noise controller together:

1. Create a sphere.
2. In the Motion panel > Parameters > Assign Controller rollout, select the Position track of the sphere.
3. Click Assign Controller and choose Position XYZ.
4. Turn on Auto Key and create three keys that move the sphere on the XY plane.
5. In the Assign Controller rollout, expand the position track and select Z Position.
6. Click Assign Controller, and then select Noise Float.
7. Play the animation. The sphere moves around the keys that were created earlier. The random up and down movement in the Z axis is generated by the noise controller on the Z track. This effect can also be created using the List Controller to combine controllers.

Interface

Motion panel > Parameters > Position XYZ Parameters rollout

X—Displays controller properties for X axis transformation.
Y—Displays controller properties for Y axis transformation.
Z—Displays controller properties for Z axis transformation.

When you select an axis, a Key Info (Basic) and Key Info (Advanced) rollout is available to change values.

A Bezier Float Controller is assigned to each track by default. Use Key Info (Basic) and Key Info (Advanced) to control how the keys behave. See Bezier Controller (page 2–310).
### PRS Controller

The Position/Rotation/Scale (PRS) controller is the default Transform controller for most objects. Use it for all general-purpose transforms.

### Procedure

**To create PRS Transform keys:**

1. Select an object.
2. Click Motion panel > Parameters.
3. Drag the time slider to the frame where you want to place a key.
4. On the PRS Parameters rollout, in the Create Key group, click one of the following:
   - Click Position to create a Position key.
   - Click Rotation to create a Rotation key.
   - Click Scale to create a Scale key.

If a particular Position, Rotation, or Scale controller does not use keys, then that button is not available in the Create Key group. For example, you cannot create Position Keys if a Noise Position controller is being used.

### Interface

**Motion panel > PRS Parameters rollout**

#### Create Key/Delete Key

The six buttons in the PRS Parameters rollout let you create or delete a transform key at the current frame. These buttons become active or inactive depending on the existence of a key type at the current frame.

For example, if you're on a frame containing a Scale key, the Scale button is inactive in the Create column, because a key already exists. At the same time, the Position and Rotation buttons are inactive in the Delete column because there are no keys of that type to delete.

**Position/Rotation/Scale**—Determines the contents of the Key Info rollouts that appear below the PRS Parameters rollout in the Motion panel.
Reaction Controllers

Track View > Highlight a track in the Track View hierarchy. > Assign a Reaction-type controller (e.g., Position Reaction).

Select an object. > Motion panel > Assign Controller rollout > Highlight a track. > Click Assign Controller > Choose a Reaction-type controller (e.g., Position Reaction).

The Reaction controller is a procedural controller that lets a parameter react to changes in any other parameter in 3ds Max. Typically, most of the setup involving Reaction controllers is done with the Reaction Manager dialog (page 2–361). You use the dialog to define a master, which is an object that controls other objects, and, for each master, any number of slaves, which are objects the master controls. Alternatively, you can assign a Reaction controller directly to a slave object using Track View or the Motion panel (as you would any other controller), and then use Reaction Manager to specify its master and other parameters.

Reaction controllers come in five different types: Position Reaction, Rotation Reaction, Point3 Reaction, Scale Reaction, and Float Reaction. You can assign a Reaction controller to any animatable track in the scene. Reaction is not based on time, but rather on other variables in your scene such as position or rotation.

You can use a Reaction controller to turn on a light as an object nears a given point. Muscles can bulge as an arm bone rotates. A ball can squash automatically as the ball’s Z position nears the ground plane. Feet can rotate as their heels are lifted from the floor.

A particle system can be triggered by any given event. Morph target percentages can be controlled by events.

Note: The Reaction controllers replace the Reactor controllers found in previous versions of 3ds Max. If you load a file containing a Reactor controller into this version of 3ds Max, the Reactor controller is converted to a Reaction controller, with all settings and reactions fully intact.

See also
Using Manipulators with Reaction Controllers (page 2–369)

Procedures

Example: To make the position of a sphere react to the position of a box:

This procedure shows an alternate way to use a Reaction controller. The recommended workflow is to do most of the setup in the Reaction Manager dialog: See Example: To use the Reaction Manager dialog: (page 2–361).

Note: Objects don’t need to be animated to use Reaction controllers. This procedure starts with animation to make the reaction easier to see.

1. On the left side of the Top viewport, create a box about 30 units on a side.
2. Animate the box from position (-100,0,0) at frame 0 to position (100,0,0) frame 100.
3. In the Front viewport, create a sphere slightly above the box. Position the sphere at (-100,0,50).
4. Go to the Motion panel, and on the Assign Controller rollout, click the Position track to highlight it.
5. On the Assign Controller rollout, click the Assign Controller button.

6. On the Assign Position Controller dialog, click Position Reaction to highlight it, and then click OK.

This opens the Reaction Manager dialog (page 2–361). The Reactions list shows that the sphere is assigned as a slave, but no master is assigned. A Reaction controller uses a master’s motion to control any number of slaves.

7. Right-click the “Unassigned” line at the top of the Reactions list. From the menu, choose Replace Master.

This places you in a Pick mode where you can choose a motion track from any object in the scene to act as master.

8. In any viewport, click the box (Box01). A pop-up menu appears.

9. From the pop-up menu, choose Transform > Position > X Position.

The “Unassigned” text is replaced by a master track labeled "Box01 / X Position".

Also, a new state, State01, appears in the States list.

This is an example of the basis of the control mechanism used by the Reaction controller: For each master/slave combination, you can specify any number of states defined by values for the master and slave tracks. The first state, created automatically when you added the master, specifies that when the box is at -100 on the X axis, the sphere should be at (-100,0,50). In this case, you’re controlling three parameters (the sphere position on all three axes) with one (the box position on the X axis). More typically you’d use one-to-one master/slave-parameter ratios.

Note: Reaction Manager also defines a state automatically when you assign a new slave to a master.

Next you’ll create a second state that tells the sphere how to move on multiple axes as the box moves on one.

10. Move the time slider to frame 50. The box moves to the midpoint of its animated trajectory. The sphere remains where it is.

11. On the Reaction Manager dialog, click the Create State button.

This creates a new state (State02) using the current positions of the box and sphere.

12. Try moving the sphere in the Front viewport.

You can’t move the sphere because it’s under the full control of its master, the box. Similarly, you can’t change its position using the Coordinate Display fields on the status bar. However, you can change the sphere’s position using the Reaction Manager’s editing tools.
13. On the Reaction Manager dialog, click the Sphere01 / Position entry to highlight it, if necessary, and then click the Edit Mode button.

14. Position the sphere at \((0,0,100)\).

The position updates in the Sphere01 / Position line under State02. Also, the Reaction Manager graph shows the change in values of the slave’s (sphere) X and Z position values as the master box’s X position changes. On the graph, as in Track View, red = X, green = Y, and blue = Z.

15. Click the Edit Mode button again to turn it off, and then scrub the time slider.

As the box moves between frames 0 and 50, the sphere rises to the position specified in the second state.

For the third and final state, you’ll have the slave move in a different direction over the second half of the master’s motion.

16. Go to frame 100, and then create a new state.

17. In the States list, click the new state or its slave track to highlight it.

18. Turn on Edit Mode. Position the sphere at \((0, -100, 100)\), and then turn off Edit Mode.

19. Scrub the time slider between frames 0 and 100.

Over the first 50 frames, the sphere moves between the first two states, and over the second half of the animation, the sphere moves between the second and third states.

To conclude the procedure, you’ll demonstrate that the sphere is responding only to the box’s X position, regardless of animation.

20. Go to frame 0. Select the box, and then press and hold the Alt key and right-click the box.

This opens the Animation quad menu.

21. From the Set (lower-right) quadrant, choose Delete Selected Animation.

This command deletes all animation keys for the current selection.

22. Now move the box in all three dimensions.

Any change in the Y or Z position has no effect on the sphere. However, moving the box between -100 and 100 on the X axis, no matter what the Y or Z position, results in changing the sphere’s position as specified in the Reaction controller.

This procedure gives you a hint of the Reaction controller’s power. You can find another procedure showing additional aspects of the Reaction Manager in: Example: To use the Reaction Manager dialog: (page 2-361).
Interface
After assigning a Reaction controller, right-click the track and then choose Properties, or choose Animation > Reaction Manager, to open the Reaction Manager dialog (page 2–361).

Reaction Manager Dialog

Procedure
Example: To use the Reaction Manager dialog:
The purpose of this procedure is to show you different ways to use Reaction Manager. Before trying it, we suggest that you first follow the introductory procedure in the Reaction Controllers topic: Example: To make the position of a sphere react to the position of a box: (page 2–358).

1. Start or reset 3ds Max.

2. In the Perspective viewport, add a box and a sphere object. Also add a Slider manipulator (page 2–31), and give it the label Slider.
The viewport should resemble the following illustration:

You'll use the slider to control two slaves separately: Negative values for the box X position, and positive values for the sphere's Hemisphere parameter.

3. On the Create panel > Parameters rollout, set Minimum to -100.0.
The slider's current value is 0.

4. Open the Reaction Manager dialog from the Animation menu and position it so you can see the Perspective viewport.
At this point, the dialog is empty.

5. On the upper toolbar, click Add Master, and then click the Slider manipulator in the Perspective viewport.

6. On the pop-up menu that appears, choose Object (Slider) > value.
In the Reactions list, the master entry Slider01 / value appears.
7. On the upper toolbar, click Add Slave, and then click the box in the Perspective viewport.

8. On the pop-up menu that appears, choose Transform > Position > X Position.

In the Reactions list, the slave entry Box01 / X Position appears under the master entry. Also, a new state appears in the States list for the newly added slave track. This simply says that, when the slider value is 0, the box’s X position should be what it is currently. However, a reaction needs at least two states to be meaningful. You’ll learn how to accomplish this shortly.

Next, you’ll discover a different way to add a slave track.

9. In the Perspective viewport, select the sphere.

10. On the upper toolbar, click Add Selected.

This causes the pop-up menu to appear at the mouse cursor.

11. From the pop-up menu, choose Object (Sphere) > Hemisphere.

The sphere’s Hemisphere track is added as a slave of the slider, and a new state for the two is added to the States list.

You now have two states in the States list, but in both cases the state value (that is, the slider value) is the same, so you really need only one. You can resolve this by adding the Hemisphere slave track to the first state and then eliminating the second state.

12. In the Reactions list, click the Sphere01 / Hemisphere entry, and in the States list, click the State01 entry.

13. On the center toolbar, above the States list, click the Append Selected button.

This adds the Hemisphere track to State01.

Now you can delete the second, superfluous state.

14. In the States list, click the State02 entry, and then on the toolbar above the States list, click the Delete State button.

State02 goes away.

Currently, the box is where you created it, but you might want it to start out at a different location. However, because the box is a slave of the slider, you can’t move it freely on the X axis. You’ll use Reaction Manager to set the X position of the box to a specific value.

15. In the States list, position the click and hold the mouse cursor over the Box01 / X Position > Value entry.
Note: Your value probably differs from that shown in the illustration.

16. Drag upward to increase the value, or downward to decrease the value. Change the value to about -50.0.
You might find it difficult to set an exact value by dragging, which changes only the tenths (and higher) value. You can use the keyboard to specify a more exact value.

17. Double-click the value.
The value highlights and becomes an keyboard-editable field.

18. Enter -50 and press Enter or Tab.
The value now displays as -50.000.
You can use the same mouse and keyboard methods to change state (master) values as well.
Next you’ll learn how to use Create Mode to create new states freely.
First you’ll set a new state to move the box leftward for negative slider values.

19. Try moving the box on the X axis.
You can’t do it, because it’s slaved to the slider value.

20. Above the States list, click the Create Mode button.
When Create Mode is on, you can change master and slave properties and use the current properties to create new states.

21. On the main toolbar, click Select And Manipulate, and then drag the slider pointer all the way to the left, so the slider value reads -100.0.

22. In the Reactions (upper) list, click the Box01 / X Position entry to highlight it, and then move the box about -50 units on the X axis, to about X=-100.
Highlighting the slave entry lets you manipulate the slaved value interactively in the viewport while Create Mode is on. Then, when you click Create State, a new state is created for that slave only. If you highlight the master instead, you can manipulate all slaves freely, but then clicking Create State creates a new state for all slaves. Reaction Manager is a complex tool, so in general it’s best to keep the data as simple as possible.

23. Click Create State.
Reaction Manager adds a new state, State02, with the state (slider) value at -100.0 and the box at its new X position.

24. Turn off Create Mode and move the slider left and right to see how it affects the box position.
Next you’ll set a new state so the right half of the slider range affects the sphere’s Hemisphere value.

25. Select the sphere and go to the Modify panel.
The Hemisphere parameter is unavailable, because it’s slaved to the slider value.

26. Turn on Create Mode, and then and in the Reactions list, click the Sphere01 / Hemisphere entry.
The Hemisphere parameter is now available.
27. On the Modify panel, set Hemisphere to 0.75.

28. In the Perspective viewport, drag the slider all the way to the right.

29. Click Create State.

   Reaction Manager adds a third state, State03, with the state (slider) value at 100.0 and the Sphere01 / Hemisphere value at 0.750.

<table>
<thead>
<tr>
<th>States</th>
<th>Value</th>
<th>Strength</th>
<th>Influence</th>
<th>Slide</th>
</tr>
</thead>
<tbody>
<tr>
<td>State03</td>
<td>0.750</td>
<td>0.800</td>
<td>1.000</td>
<td></td>
</tr>
<tr>
<td>Sphere01 / Position</td>
<td>50.000</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Sphere01 / Hemisphere</td>
<td>0.800</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>State02</td>
<td>100.000</td>
<td></td>

<td></td>
</tr>
<tr>
<td>Sphere02 / Position</td>
<td>100.000</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Sphere02 / Hemisphere</td>
<td>1.000</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

   Also, if you click Slide01 / value in the Reactions list, you can see in the graph showing the slider value on the horizontal axis and the two reactions on the vertical axis. The scale between the two differs greatly, so the Hemisphere reaction on the right side of the graph looks like a straight line, but if you click the Sphere01 / Hemisphere slave entry in the Reactions list, the graph shows a steady rise from 0.0 to 0.75.

30. Turn off Create Mode and then drag the slider in both directions.

   Over the left half of the slider range, the box moves along the X axis, and over the right half of the range, the sphere’s Hemisphere value changes.

   To finish the procedure, you’ll experiment with using the graph to change a reaction.

31. If you haven’t already, click the Sphere01 / Hemisphere slave entry in the Reactions list, and then click Zoom Extents button below the graph.

32. Click the Add Point button, and then click the middle of the graph curve (it’s the red, diagonal line).

   This adds a new point to the curve and a new state in the States list.

33. Click the Move button, and then drag the new point upward so it’s above the right-hand endpoint.

34. Drag the slider again.

   As the slider moves from 0 to 100, the Hemisphere value increases so much that the sphere disappears, and then decreases so you can see the upper fourth of the sphere.

   This has been a brief tour of some of the capabilities of the Reaction Manager dialog. For further information, consult the reference, below.

### Interface

The Reaction Manager dialog interface consists of three parts: the Reactions list, the States list, and
the graph. Each has its own toolbar or toolbars. Each list contains rows and columns; the column headings employ standard Windows functionality.

To resize a column, drag the divider to the right of its heading, or auto-size a column to fit its widest entry by double-clicking the right-side heading divider. To change the vertical size of a list section, drag the horizontal divider at the bottom of the list, and to scale all three sections proportionally, drag the bottom of the dialog. You can also resize the dialog by dragging a corner or a side.

You can use standard methods to highlight list items for further actions. Highlight a single item by clicking it. Highlight multiple consecutive items by clicking the first item and then Shift + clicking the last. Use Ctrl + click to highlight non-contiguous items and to toggle highlighting of a single item.

In most cases, if a cell in the Reactions list or the States list contains a single numeric value, you can change the value by dragging vertically on the cell. Click and hold on the number in the cell, and then move the mouse upward to increase the value or downward to decrease it. The exception to this are the Start and End frames for master objects; you can change these values only by modifying a slave’s Start or End value. You can also modify a one-value field by double-clicking it and then editing it with the keyboard. If a field contains multiple numeric values, you must manipulate the object directly in the viewports or the appropriate dialog.

The dialog also has a right-click menu (page 2–368) for managing reactions and states, available by right-clicking anywhere on the dialog except in the graph section.

Note: A master is an object that you can use to control other objects via Reaction controllers, and a slave is an object controlled by a master.

### Reactions list

<table>
<thead>
<tr>
<th>Reaction</th>
<th>Start</th>
<th>End</th>
<th>Curve</th>
<th>Show-Selected</th>
</tr>
</thead>
<tbody>
<tr>
<td>Slide 1 Y value</td>
<td>0</td>
<td>100</td>

<td></td>
</tr>
<tr>
<td>Bone 1 Y Rotation</td>
<td>0</td>
<td>100</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Bone 1 Y Rotation</td>
<td>0</td>
<td>100</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The Reactions list displays a hierarchical view of the master-slave relationships of objects with Reaction controllers in the scene. You can use its controls to add and delete masters and slaves, change start and end frames, and toggle usage of the graph curve. These controls are available both on the toolbar above the list and in the list itself.

**Add Master**—Places you in Add Master mode. Click an object in a viewport, and then use the pop-up menu to choose an animation track to use as master. Alternatively, choose a track in Track View or from the Motion panel > Assign Controller rollout list.

Using the pop-up menu, you can choose only a track at the end of the menu hierarchy; for example, Transform > Position > X Position. If you choose the object name from the top of the menu, Reaction Manager lists it as World Space Position, so that you can use its three-dimensional position in the World coordinate system to control its slaves.

To use a Position or Rotation track for the master, click Add Master and then click the track in Track View or the Motion panel > Assign Controller rollout list. In the latter case, the object must already be selected in the viewports before clicking Add Master in order for it to show up on the Assign Controller rollout list. If using Track View, you can open the Track View dialog before or after clicking Add Master.

**Tip:** If you use Track View or Motion panel to assign a Reaction controller to an animation track, the object shows up in Reaction Manager without a master (“Unassigned”). To assign a master,
right-click the highlighted “Unassigned” label, and then choose Replace Master from the context menu. Finally, choose the master track.

Add Slave—Places you in Add Slave mode, letting you assign a slave track to the currently highlighted master in the Reactions list. Highlight a master and then click Add Slave. Click an object in a viewport, and then use the pop-up menu to choose an animation track to use as slave. Alternatively, choose a track in Track View or from the Motion panel > Assign Controller rollout list. Available only when a master is highlighted in the Reactions list.

To add multiple slaves, click Add Slave and then press \( H \) to open the Pick Object dialog. Highlight the objects to add, and then click Pick. The pop-up menu then appears, prompting you to choose an animation track to use as slave. The same track is used from each object. Alternatively, select the objects and then use Add Selected (see following).

If multiple masters are highlighted when you add a slave or slaves, the slave is added to the first master in the list.

If any states are highlighted in the States list, the new slave or slaves are added to the highlighted states. If no states are highlighted in the States list, Reaction Manager creates a new state with the added slave or slaves.

Delete Selected—Deletes any items highlighted in the Reactions list.

If you delete a slave, any related state definitions are deleted from the States list, although the states themselves remain. If you delete a master, all of its slaves and any related states are also deleted.

Show Selected—When on, displays data in the Reactions list only for objects selected in the viewports. This lets you restrict display reaction setups to objects of immediate interest, without having to scroll through long lists of parameters.

When off, shows all objects and states, regardless of viewport selection status.

If the master is selected in the viewport, Show Selected shows all slaves in the Reaction list whether or not they’re selected.

Update Selection—Refreshes the list contents based on the current selection. Available only when Show Selected is on and the viewport selection has changed.

Start/End—These columns show the first and last animation frames for which the master-slave relationship is in effect. These default to the active time segment (page 3-904). Use standard methods to change these values.

If multiple slaves assigned to the same master have different Start or End values, the master’s Start and End fields are blank.

Curve—This column shows an X when the graph curve (page 2–368) is used to modify Strength, Influence, and Falloff. To specify these numerically
in the States list, click the field to toggle the X. Available for slaves only.

**States list**

A state describes interaction between a master and its slaves. In each state, you specify a value or values for the master track, and corresponding values for each slave. Then, as a master-track value changes in the scene, the slaved values follow along according to the states’ specifications.

The States list shows all states for the highlighted reaction in the Reactions list. Any member of a reaction (master and/or slaves) can be highlighted in the Reactions list for its states to appear in the States list. If members of multiple reactions are highlighted, the States list reflects values for the first highlighted reaction only.

You can use tools in the States list to add and modify states and their names. To change a state name, click the text twice, slowly (don’t double-click). Or, if the state name already highlighted, just click it once. The text highlights and a box appears around it to show that you can now edit it. You can rename only state names, not the indented slave tracks.

You can change values for single-numeric-value slaves in this list by dragging vertically on the value.

The following reference describes changing values interactively in the viewports using the States list controls. Other controls are described in the introduction to this topic.

**Create Mode**—Use primarily to create new states interactively. To use it, turn on Create Mode, adjust values for the current reaction (master and slaves) in the viewports, and then click Create State. You can repeat this to create any number of new states quickly and efficiently.

The difference between creating a state in or out of Create mode is that, in Create mode you can manipulate the reaction tracks for all objects, whereas with it off you can manipulate the reaction track only for the master.

**Create State**—Adds a new state to the States list for the current reaction, using the current values for the master and slave parameters.

When you create a state, the software gives it a default name (State##) and lists its slave tracks, indented, under the state name.

The contents of the new state depend on what’s highlighted in the Reactions list. If the master is highlighted, a new state specifies values for the state (i.e., master track) and all of its slaves. If one or more slaves are highlighted in the Reactions list, the new state specifies values for the master and only the highlighted slaves.

**Append Selected**—Adds a slave or slaves to a state in which they don’t currently participate. To use, highlight one or more slave tracks in the Reactions list, highlight a state in the States list, and then click Append Selected.

**Edit Mode**—When on, you can change slave values interactively in the current state by manipulating slave objects in the viewports or by editing their values on a rollout. Available only when at least one item in the States list is highlighted.

If you highlight a slave name, you can edit its value for the current state. If you highlight a state name and then click Edit Mode, you can edit any of its slave tracks. To exit this mode and test the new values, click Edit Mode again.
As you manipulate the object, the value is updated immediately and the new value is displayed in the States list. If slaves in multiple states are highlighted, values are updated for those in the first state only.

**Set State**—Updates the highlighted state (master track) to its current value. To use this option, highlight the master track in the Reactions list and the state in the States list. Manipulate the master object in the viewports, and then click Set State to update the state value. Available only when a state is highlighted in the States list.

**Delete State**—Deletes any items highlighted in the States list.

**Value**—This column shows the current value or values for the state: the master parameter(s) on the State## line and the slave parameter(s) on each slave line within a state. You can edit a single value (not groups of three in parentheses) by dragging vertically on the value in the table.

The following three parameters, which appear as columns in the States list, apply to slaves and are normally controlled via the graph curve. They’re available only if the slave has Curve turned off in the Reactions list.

These parameters are based on the fact that states can influence one another, so that you get a blending between them.

**Strength**—This is a biasing factor that affects a state’s relative influence when one or more states overlap. A greater Strength value influences a value towards a state and a smaller one influences the value away from it.

**Influence**—The distance from the master state’s value to the maximum extent of its range of influence.

**Falloff**—The rate of change in the slave state (its speed) as the master goes from a state to the maximum extent of its range of influence.

**Graph**

Reaction Manager’s graph displays curves that graph the master values on the horizontal axis and slave values on the vertical axis. It shows data of all states for items highlighted in the Reactions list. If a master is highlighted, the graph shows states curves for all its slaves. If one or more slaves are highlighted, but the master isn’t, the graph shows data for those slaves only. You can edit data using the graph by dragging points.

The graph controls are similar to those found in other graphs in 3ds Max, such as the Material Editor Output rollout (page 2–1621). The toolbar above the graph offers functions for moving and scaling points on the graph, as well as inserting new ones (that is, new states). The same functions are available by right-clicking the graph, and if you right-click a graph point, you can set it to Corner and two different Bezier types. If you select a Bezier point, you can reshape the curve by moving its handles. You can drag a region to select multiple points, and then edit them together. Use the toolbar under the graph for panning and zooming the graph.

**Right-click menu**

Reaction Manager’s right-click menu provides quick access to a number of commonly used functions. It also contains the Replace Master function, which is unavailable elsewhere in the
dialog interface. To open the right-click menu, right-click anywhere on the Reaction Manager dialog except in the graph section.

**Add Master**—Places you in Add Master mode. Click an object in a viewport, and then use the pop-up menu to choose an animation track to use as master. Alternatively, choose a track in Track View or from the Motion panel > Assign Controller rollout list.

For more information, see Add Master.

**Replace Master**—Lets you replace the current master. Use the standard method to choose another master as described in Add Master.

Use this function to specify a master when you open Reaction Manager by assigning a Reaction controller to a slave.

**Note:** If you replace a master with multiple states, Reaction Manager deletes all existing states except the default one. In essence, replacing a master is like starting over.

**Add Slave**—Lets you add a slave to the current master. For details, see Add Slave.

**Add Selected**—Lets you add selected objects as slaves to the current master. For details, see Add Selected.

**Delete Selected**—Deletes any items highlighted in the Reactions list. For details, see Delete Selected.

**Create States Mode**—Lets you create states on the fly by manipulating objects in the viewports. For details, see Create Mode.

**Create State**—Adds a new state to the States list for the current reaction. For details, see Create State.

**Append Selected**—Adds a slave to a state in which the slave doesn’t currently participate. To use, highlight a slave in the Reactions list, highlight a state in the States list, and then choose Append Selected.

**Set State**—Updates the highlighted state (master track) to its current value. For details, see Set State.

**Delete State**—Deletes any highlighted items in the States list.

**Edit Slave State Mode**—Lets you change slaves’ values in the current state. For details, see Edit Mode.

**Show in Track View**—Opens Track View, displaying reaction tracks for highlighted slaves and masters only.

**Show in Schematic View**—Opens Schematic View, with reaction tracks expanded for highlighted slaves and masters.

---

### Using Manipulators with Reaction Controllers

The Position Reaction and Rotation Reaction controllers (page 2–358) let you perform certain functions via manipulators in the viewports.

#### Procedure

**To use manipulators for a position or rotation Reaction controller:**

(Point3, scale, and float Reaction controllers don’t have manipulators.)

1. Select the object that has the Reaction controller assigned to it.

2. On the default Main toolbar, click Select And Manipulate.

The manipulators appear in viewports.

3. In the active viewport, drag or click manipulators to adjust the reaction parameters.

When you move the mouse over a manipulator, the manipulator turns red to show that dragging or clicking it will have an effect.
Tip: Use the reactor manipulators in a wireframe viewport. (See Viewport Right-Click Menu (page 3–731).) Also, for the Position Reaction controller, you might have to change viewports to see a particular manipulator clearly.

The specific manipulators and their use are described below.

**Manipulators for Reactor Controllers**

Reaction controllers for position and rotation tracks have graphic manipulators to help you adjust their settings.

Other Reaction controllers, such as point3, scale, and float, do not have manipulators.

Manipulators are visible and usable while the Select and Manipulate button (page 2–15) is turned on. This button is on the default main toolbar (page 3–686). When you move the mouse over a manipulator, the manipulator turns red to show that dragging or clicking it will have an effect.

Tip: Use the Reaction controller manipulators in a wireframe viewport. (See Viewport Right-Click Menu (page 3–731).) Also, for the Position Reaction controller, you might have to change viewports to see a particular manipulator clearly.

**Position Reaction controller**

The Position Reaction controller has a set of manipulators to control (or simply display) different reaction values.

**Reaction cycle manipulator:** Click this to cycle among the various reactions in the Reactions list. The display of the manipulators and indicators changes to show their settings for the active reaction.

This manipulator is a small yellow circle that appears in the lower-left corner of the active viewport, near the icon for coordinate axes.

**Influence manipulator:** Drag in a viewport to change the manipulator’s size, which changes the reaction’s range of influence.

This manipulator is a yellow sphere that turns red when you can drag it. At the center of the Influence manipulator is the Reaction Value manipulator.

**Reaction Value manipulator:** Drag in a viewport to change the reaction value, which for a position track is an XYZ location.

This manipulator is a light blue sphere that appears at the center of the Influence manipulator.

**Object Pivot indicator:** Shows the pivot point location of the master object.

This indicator is a dark blue sphere. You can’t manipulate it.

**Reaction State manipulator:** Drag to adjust the reaction state. For position reactions, the reaction state is an XYZ location that the slave object approaches, depending on the animation of the master object and the Influence value.

This manipulator is a small green square.

**Reaction State indicator:** Shows the reaction state value. This indicator is independent of the square green Reaction State manipulator, which you can drag in viewports. As you drag the green square, the indicator follows it.

This indicator is a small dark-blue dot.

**Rotation Reactors**

The Rotation Reaction controller has a single manipulator, which controls the reaction’s Influence parameter.

**Influence manipulator:** Drag in a viewport to change the manipulator angle, which changes the reaction’s range of influence.
Scale XYZ Controller

The Scale XYZ controller has independent float controllers for each scale axis of an object's transform. With three separate tracks for scale, you can create scale keys for each axis independently, change interpolation settings for a single axis, or assign a controller on an axis. For example, after applying a Scale XYZ controller, you could apply a Noise or Waveform controller to an axis to animate that axis independently.

The Scale XYZ controller assigns three keys (one for each axis), by default. In previous versions of the software, you had to edit the keys manually in order to create explicit axis keys. However, there are now actions available from the Customize User Interface dialog (page 3–792) that let you create explicit axis keys (page 2–297).

Tip: Open Track View to view and edit the three scale tracks.

Procedure

Example: To assign the Scale XYZ controller to an object:

1. In the Top viewport, create a sphere.
2. Right-click over the sphere and choose Curve Editor from the quad menu.
3. In the Track View hierarchy, click the Scale track.
4. From the Track View menus, choose Controller > Assign and select Scale XYZ from the Assign Controller dialog.
   Three tracks are displayed and are available to control the object’s scale.
5. In the Track View hierarchy, click the Z Scale track, click Controller > Assign from the Track View menus, and then choose Noise Float from the dialog.
   The Noise Controller dialog automatically displays.
6. Click Play. The sphere changes scale along the Z axis, controlled by the Noise controller.

Interface

After applying the Scale XYZ controller to an object, Scale XYZ parameters appear in a rollout on the Motion panel.

Scale Axis—Adjusts an axis using controls in the Motion panel > Key Info rollout.

An axis should already have a key to adjust. To create keys, either turn on Auto Key and scale the object, or click Scale in the Create Key group on the PRS Parameters rollout.
Script Controller

Main toolbar > Curve Editor (Open) > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Script

Graph Editors > Track View - Curve Editor > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Script

The following Script controllers are available in the software:

- Float Script - float controller
- Position Script - position Point3 controller
- Point3 Script - Point3 controller
- Rotation Script - rotation Quaternion controller
- Scale Script - scale Point3 controller
- Transform Script (page 2–379) — matrix3 PRS controller

The Script controllers work similarly to Expression controllers (page 2–320). They provide a Script Controller dialog where a script can be entered for computing the controller value. The primary advantages of Script controllers are:

- They can use all the features of the MAXScript language, including loops, scripted functions, and path names.
- Almost any property of any object in a scene can be used to help compute controller values, including mesh vertices, values of properties at arbitrary frame times, and other non-animatable properties that are not accessible in Expression controllers.
- They can use MAXScript global variables to communicate and coordinate with other controllers and scripts in the software.

Refer to the MAXScript Reference for a complete explanation of this scripting language.

Writing Controller Scripts

3ds Max interprets the text you type into the Script text box as the body of a MAXScript block expression. You can type as many expressions as you want on as many lines as you want, and they are evaluated in turn. The value of the last expression is taken as the controller value. This value must yield the right type for the controller: Float for float, Point3 for position, Quat for rotation, and so on.

Because the text is inside a block expression, you can declare local variables that are visible only within the script and are temporary for one evaluation. You can also declare or access global variables that are shared with all other scripts in MAXScript and hold their values from one evaluation to the next.

A controller is always evaluated by 3ds Max with respect to a specific animation time. This might be the current time slider or incrementing frame time if an animation is playing, or a rendering is under way. In the case of Script controllers, the time being evaluated is used to establish an automatic "at time" context around the controller script, so any properties you access (outside of other explicit "at time" expressions) yield the correct values for the current controller evaluation time. This means you don’t have to do anything special in your scripts to work at the correct time. You can access the evaluation time with the standard MAXScript variable, currentTime. You can also reference scene property values at other times by using “at time” expressions in your scripts, as in regular MAXScript programming.

Assign Nodes and Tracks to Variables

When you need to refer to nodes in your scene or to animation tracks, it is recommended that
you use the Script controller variable toolset to create variables to assign to any particular node or controller track. This way, if you decide to later on rename your scene objects, the script controllers using these objects are preserved because the variables maintain the link to the nodes.

Otherwise, if you assign, for example, a node to a variable manually in the dialog’s Expression window, that link becomes broken as soon as you rename that particular node.

Note: It is especially important to assign nodes and tracks to variables with the corresponding buttons when using XRef scenes and objects.

Procedure

Example: To keep an object centered relative to other objects in the scene during an animation:

1. Name the object that should remain centered foo and assign a Script controller to its Position track.
2. Enter foo in the Name field and click Create. The new variable is automatically added to the Variables list.
3. With the variable highlighted, click Assign Node. The Track View Pick dialog opens, listing the contents of your scene.
4. Expand the Objects hierarchy until you locate foo. Highlight it and click OK. The foo node is assigned to your variable.
5. Enter the following script in the Script Controller dialog’s Expression window:

   ```lisp
   local pos=[0,0,0]
   for o in objects where o != foo do
     pos += o.pos
   pos / (objects.count - 1)
   ```

   This script computes the average position of all objects, except the current one (written as foo here) by setting up a local, iterating over all objects except foo, accumulating a total position vector, and computing the average in the last line, which is the final result of the script.

Assigning a Script controller automatically opens a Script Controller dialog where you can enter a script. You can open the dialog subsequently by right-clicking the track on the Motion panel or in the Track View hierarchy and choosing Properties, or clicking the Properties button on the Track View toolbar.

Tip: You can resize the dialog by dragging an edge or a corner.

Create Variable group

Name—Lets you enter and edit the name of user variables.

Create—Creates a variable and adds it to the Variables list.

Delete—Removes the highlighted variable from the Variables list. You can also delete a variable by tying its name into the Name field and click Delete.

Rename— Renames the highlighted variable.

Variable Parameters group

Tick Offset—Specifies a time offset in ticks for the current variable. When the script is evaluated, the variable’s value is set from the current time plus the Tick Offset value.
Note: The Time Offset has no effect on variables that are assigned a constant.

**Variables List**—Lists all available variables in the controller. The following pre-defined constant variables are available in every script Controller and cannot be deleted or renamed:

- **F**—the current time in frames
- **NT**—the normalized time
- **S**—the current time in seconds
- **T**—the current time in ticks

**Assign Constant**—Opens a dialog which lets you assign a constant to the highlighted variable.

**Assign Controller**—Lets you assign a track to the highlighted variable.

**Assign Node**—Lets you assign a node to the highlighted variable.

**Expression text field**—Enter the script expression here to calculate the controller value.

**Description text field**—Enter comments regarding the functionality of the controller.

**Value expression**—Enter any MAXScript value (such as an integer, a float, an array, etc.) or expression.

**Value expression result**—Displays the results of the expression above.

**Evaluate**—Analyzes your expression at the current time.

**OK**—Assigns the value expression result to the current variable.

**Cancel**—Disregards the current value expression result and closes the dialog.

**Assign Track**—Lets you assign a controller to the highlighted variable. The controller’s value is taken at the current time plus the variable’s Tick Offset.

**Smooth Rotation Controller**

Use Smooth Rotation when you want rotation to have a smooth and natural look. Smooth rotation
functions the same as Linear Rotation, but uses non-adjustable curved interpolation, and has the following characteristics:

- Displays no controllers, key properties, or function curves
- Move keys in Track View to change timing
- Directly rotate objects in the viewports to change rotation values

### Spring Controller

Main toolbar > Curve Editor (Open) > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Spring

Graph Editors > Track View – Curve Editor > Select a track in the Track View hierarchy. > Track View toolbar > Controller menu > Assign > Spring

Animation menu > Position controllers > Spring

The Spring controller adds secondary dynamics effects to any point or object position. The end result is secondary mass/spring dynamics similar to Flex. This constraint adds realism to generally static animations.

When you apply Spring to an animated object, its original motion is preserved and secondary, velocity-based dynamics are applied. You can control the object’s mass and drag. When you first apply the controller, it constructs a virtual spring between the object’s original position and where it would end up after forces are applied to it.

You can adjust spring tension and dampening. Increasing the tension creates a tighter spring, while increasing the dampening smooths out jitters in the motion. You can add external forces like Gravity (page 2–73) and Wind (page 2–75) to affect the motion, and also add additional objects whose motions act as springs.

Note: You can also assign the Spring controller to animated vertices in Track View: Open the object’s Master Point Controller hierarchy, select the vertices, and assign the Spring controller.

### Interface

When you assign a Spring controller to an object, its rollouts automatically appear in the Motion panel. In addition, the rollouts open in a floating dialog. If you close the dialog, you can reopen it by right-clicking the track in the Motion panel Assign Controller rollout or in the Track View hierarchy and choosing Properties, or clicking the Properties button on the Track View toolbar.

### Spring Dynamics rollout

You can adjust spring tension and dampening.
Point group

**Mass**—The mass of the object to which the Spring controller is applied. Increasing the mass causes the "bouncing" spring motion to become more exaggerated.

**Drag**—Acts as air friction on the spring motion. A low Drag setting results in a greater "bouncing" effect, while a high Drag results in subdued bouncing. Default=1. Range=0 to 10.

Springs group

Add springs to an object using the Spring controller when you want the object to be affected by the motion of other objects in your scene. This effectively creates virtual springs between objects.

**Add**—Click this button, and then select one or more objects whose motion relative to the spring-controlled object will act as springs on that object. To finish adding springs, click Add again, right-click in a viewport, or press \[Esc\].

**Remove**—Removes highlighted spring objects from the list.

**List**—Lists all spring objects by name, and displays each object's Tension and Dampening settings separated by a slash (/). The spring-controlled object's influence on itself appears as Self Influence, and cannot be deleted. However, you can effectively remove the object's influence on itself by setting Tension and Dampening to 0, resulting in no motion.

To set Tension and Dampening for one or more objects in the list, highlight them in the list and then adjust the settings.

**Tension**—The "stiffness" of the virtual spring between the controlled object and the highlighted spring object(s).

**Dampening**—Acts as a multiplier of an internal factor that determines how quickly the object comes to rest.

With the Self Influence spring, changing Dampening has the same effect as changing Drag. With other springs, Dampening affects only the movement caused by that spring.

Internally, the dampening value is proportional to the tension, so as you increase the tension and make the solution more stiff, the dampening is increased to maintain system stability.

**Relative/Absolute**—With Relative chosen, changing the Tension and Dampening settings causes the new settings to be added to the existing values. With Absolute chosen, the new settings replace the existing values.

Forces Limits and Precision rollout

**External Forces**

**Add**—Click this button, and then select one or more space warps in the Forces category that are to...
affect the object’s motion. To finish adding space warps, click Add again, right-click in a viewport, or press [Esc].

Remove—Removes highlighted space warps from the list.

(List)—Lists all spring space warps by name.

Calculation Parameters group
Start Frame—The frame at which the Spring controller first takes effect. Default=0.

Iterations—The accuracy of the controller application. If you get unexpected results, try increasing this setting. Default=2. Range=0 to 4.

X/Y/Z Effect—These settings let you control the percentage of the effect on the individual world axes. Default=100. Range=0 to 200.

TCB Controllers

This controller works well as a Position controller in conjunction with the Motion panel > Trajectories display of an object. With sub-object keys turned on and the Key Info dialog for a key displayed (right-click and select Key Info on the selected key to display Key Info properties), you can change the parameters in the Key Info dialog and see the trajectory path change. This allows for very precise control of an object’s trajectory with visual feedback.

Euler XYZ is now the default rotation controller in 3ds Max. The TCB Rotation controller was the default rotation controller for files created in versions 4 and earlier.

Tip: Euler XYZ behaves very differently than TCB rotations. Users upgrading from versions 4 or earlier might have difficulty adapting to the differences between these controllers. If you are used to working with TCB rotations, you can reassign it to be the default rotation controller.

Procedure

To change an Euler XYZ Rotation controller into a TCB Rotation controller:

1. Select an object animated with an Euler XYZ rotation controller.

2. In Motion panel > Parameters > Assign Controller rollout, select the Rotation track in the list window.

3. Click Assign Controller, and then select Quaternion (TCB).

You can also assign this controller in Track View or from the Animation menu.
TCB controllers display their properties in a Key Info dialog in Track View and a single Key Info rollout in the Motion panel.

**Time field**—Specifies when in time the key occurs.

**Time Lock**—Prevents horizontal key motion in Track View edit modes.

**Key Value fields**—Stores the animation values for the key. The number and meaning of the fields vary with different parameter data types. Some typical field arrangements are:
- XYZ fields for Position and Point3 keys
- XYZ percentage fields for Scale keys
- A single value field for Float keys

**TCB Graph**—Charts the effect that changing the controller properties will have on the animation. The red mark at the top of the curve represents the key. The marks to the left and right of the curve represent an even division of time to either side of the key.

The TCB graph is a stylized representation of the animation around a single key. If you want to view the effect of changing TCB properties on the true animation curve, use the Function Curves mode of Track View (works only with position and scale).

The following descriptions refer to both the TCB graph and the function curve as the animation curve.

**Note:** When you are changing the properties of a selection of multiple keys, the TCB graph is blank unless all properties are equal.

**Ease To**—Slows the velocity of the animation curve as it approaches the key. Default=0.

High Ease To causes the animation to decelerate as it approaches the key.

The default setting causes no extra deceleration.

**Ease From**—Slows the velocity of the animation curve as it leaves the key. Default=0.

High Ease From causes the animation to start slow and accelerate as it leaves the key.

The default setting causes no change of the animation curve.

**Tension**—Controls the amount of curvature in the animation curve.

High Tension produces a linear curve. It also has a slight Ease To and Ease From effect.

Low Tension produces a very wide, rounded, curve. It also has a slight negative Ease To and Ease From effect.

The default value of 25 produces an even amount of curvature through the key.

**Continuity**—Controls the tangential property of the curve at the key. The default setting is the only value that produces a smooth animation curve through the key. All other values produce a discontinuity in the animation curve causing an abrupt change in the animation. Default=25.

High Continuity values create curved overshoot on both sides of the key.

Low Continuity values create a linear animation curve. Low continuity creates a linear curve.
similar to high tension except without the Ease To and Ease From side effect.

The default setting creates a smooth continuous curve at the key.

**Bias**—Controls where the animation curve occurs with respect to the key. Default=25.

High Bias pushes the curve beyond the key. This produces a linear curve coming into the key and an exaggerated curve leaving the key.

Low Bias pulls the curve before the key. This produces an exaggerated curve coming into the key and a linear curve leaving the key.

The default setting distributes the curve evenly to both sides of the key.

**Rotation Windup (TCB rotation only)**—When on, rotation keys can be greater than 180 degrees. When off, rotation keys are always less than 180 degrees. This is useful if you want to set a single rotation key to create multiple revolutions of an object. Default=off.

**Warning:** If you have Rotation Windup on and you insert a rotation key between two previously created rotation keys, you might get unexpected directional shifts. Rotation Windup works best if you set keys using a straight-ahead workflow.

The Transform Script controller contains all of the information contained in a Position/Rotation/Scale (PRS) controller (page 2–357) in one scripted matrix value. Instead of having three separate tracks for position, rotation, and scale, all three values can be simultaneously accessed from one script controller dialog. Because the transform values are defined by a script, they are easier to animate.

The value of the controller script must be a matrix3 value. A matrix3 value is a 4x3 3D transformation matrix. For more information, see the Matrix3 Values topic in the MAXScript reference.

**Writing Controller Scripts**

The software interprets the text you type into the Script text box as the body of a MAXScript block expression. You can type as many expressions as you want on as many lines as you want, and they are evaluated in turn. The value of the last expression is taken as the controller value. This must yield a matrix3 value.

Since the text is inside a block expression, you can declare local variables that are visible only within the script and are temporary for one evaluation. You can also declare or access global variables that are shared with all other scripts in MAXScript and hold their values from one evaluation to the next.

A controller is always evaluated with respect to a specific animation time by the software. This might be the current time slider or incrementing frame time if an animation is playing, or a rendering is under way. In the case of Script controllers, the time being evaluated is used to establish an automatic “at time” context around the controller script, so any properties you access (outside of other explicit “at time” expressions) yield the correct values for the current controller evaluation time. This means you don’t have to do anything special in your scripts to work at the correct time. You can access the evaluation...
time with the standard MAXScript variable, current Time. You can also reference scene property values at other times by using "at time" expressions in your scripts, as in regular MAXScript programming.

**Assign Nodes and Tracks to Variables**

When you need to refer to nodes in your scene or to animation tracks, it is recommended that you use the Script controller variable toolset to create variables to assign to any particular node or controller track. This way, if you decide to later on rename your scene objects, the script controllers using these objects are preserved because the variables maintain the link to the nodes.

Otherwise, if you assign, for example, a node to a variable manually in the dialog’s Expression window, that link becomes broken as soon as you rename that particular node.

**Note:** It is especially important to assign nodes and tracks to variables with the corresponding buttons when using XRef scenes and objects.

**Procedure**

**To use a Transform Script controller:**

1. Select an object.
2. Right-click to open the quad menu.
3. In Transform quadrant, click Curve Editor.
4. Select the Transform track of the selected object in Track View.
5. Select Transform Script from the Assign Transform Controller dialog and click OK. The Script Controller dialog opens.
6. Edit the matrix 3 value in the Script Controller dialog, and click Evaluate when you are finished.

**Interface**

After assigning a Transform Script controller, a Properties dialog is available by right-clicking the track in the Track View hierarchy and choosing Properties.

**Create Variable group**

**Name**—Lets you enter and edit the name of user variables.

**Create**—Creates a variable and adds it to the Variables list.

**Delete**—Removes the highlighted variable from the Variables list. You can also delete a variable by tying its name into the Name field and click Delete.

**Rename**—Renames the highlighted variable.

**Variable Parameters group**

**Tick Offset**—Specifies a time offset in ticks for the current variable. When the script is evaluated, the variable’s value is set from the current time plus the Tick Offset value.

**Note:** The Time Offset has no effect on variables that are assigned a constant.

**Variables List**—Lists all available variables in the controller. The following pre-defined constant variables are available in every script Controller and cannot be deleted or renamed:

- **F**—the current time in frames
- **NT**—the normalized time
- **S**—the current time in seconds
- **T**—the current time in ticks
**Assign Constant**—Opens a dialog which lets you assign a constant to the highlighted variable.

**Value expression**—Enter any MAXScript value (such as an integer, a float, an array, etc.) or expression.

**Value expression result**—Displays the results of the expression above.

**Evaluate**—Analyzes your expression at the current time.

**OK**—Assigns the value expression result to the current variable.

**Cancel**—Disregards the current value expression result and closes the dialog.

**Assign Track**—Lets you assign a controller to the highlighted variable. The controller’s value is taken at the current time plus the variable’s Tick Offset.

**Assign Controller**—Lets you assign a track to the highlighted variable.

**Assign Node**—Lets you assign a node to the highlighted variable.

**Expression text field**—Enter the script expression here to calculate the controller value.

**Description text field**—Enter comments regarding the functionality of the controller.

**Load/Save**—Load and save scripts to text files.

**Debug**—Opens the Script Controller Debug Window, which displays the value of all variables used in your script.

**Evaluate**—Evaluates the script expression. The evaluation is computed for the current position of the time slider.

**Close**—Compiles and checks the controller script for errors. If no errors are found, the dialog is closed. Any problems result in a query box asking whether you want to revert the expression to the original value of the current track and close the dialog (OK), or to return to editing the expression (Cancel).

---

**Waveform Controller**

Main toolbar > Curve Editor (Open) > Select a track in the Track View hierarchy. > Track View menu bar > Controller menu > Assign > Waveform Float

Graph Editors > Track View – Curve Editor > Select a track in the Track View hierarchy. > Track View toolbar > Controller menu > Assign > Waveform Float

The Waveform controller is a float controller that provides regular, periodic waveforms. Created originally to control blinking lights, you can use it on any float value.

To view how the trajectory of an object is being affected by the Waveform controller, turn on Motion panel > Trajectories.
Procedure

To use the Waveform controller to animate the visibility of a sphere:
1. Create a sphere.
2. Open Track View, and select the Sphere track.
3. On the Tracks menu choose Visibility Track > Add.
4. Select the Visibility track, click Controller > Assign, and select Waveform Float.
5. Play the animation to see the effect.

To use the Waveform controller to animate the radius of a sphere:
1. Create a sphere.
2. Open Track View — Dope Sheet, and expand the Object (Sphere) track.
3. Select the Radius track, click Controller > Assign, and choose Waveform Float from the Assign Controller dialog.
4. Play the animation to see the effect.

Interface

After assigning the Waveform controller, in Track View, right-click its track to display its properties in the Waveform Controller dialog.

List Window—Displays waveforms in a list.
Add—Adds a new waveform to the end of the list. The default waveform is a sine wave with a period of 10 frames and with an amplitude of 100.

Insert—Inserts a new waveform before the selected waveform slot.
Remove—Deletes the selected waveform. This is not available when only one waveform remains.
Move Up and Move Down—Shifts the selected waveform up and down in the list, allowing the waveform order to be altered.
Disable—Disables the selected waveform.

Waveform group

This group provides control parameters for the currently selected waveform.

Tip: Using the Sphere example, you can observe the waveform in the Function Curve displays of the Track View, and watch changes in the waveform while testing the parameters described below.

Name—Contains the name of the waveform.
Waveform Icons—Specifies five waveform types: Sine, Square, Triangle, Sawtooth, and Half Sine.
Inverted—Flips the waveform vertically.
Flipped—Flips the waveform horizontally.
Period—Sets the number of frames to complete one waveform pattern. Spinner Value=float, 0.01 to 9,999,999
Duty Cycle—For square waves only, specifies the percentage of time the square wave is “on.” Default=50, Spinner Value=float, 0 to 100
Amplitude—Sets the height of the wave. Spinner Value=float, 0 to 9,999,999
Phase—Sets the offset of the wave. Spinner Value=float, 0 to 1

Vertical Bias group

A waveform’s output value can be altered by adjusting the Vertical Bias parameter. Spinner Value=float, -9,999,999 to 9,999,999
Centered—Centers the waveforms vertical bias about zero. For example, a 100 unit amplitude waveform would range from -100 to 100.

Auto > 0—Shifts the waveform above the zero line.

Auto < 0—Shifts the waveform below the zero line.

Manual—Lets you set the waveform manually by adjusting the spinner.

Effect group
Each waveform has an Effect parameter, which can be one of the following:

Add—Causes the current waveform’s value to be added to the previous waveform’s output. This is the default.

Multiply—Multiplies the previous waveform’s output by this waveform’s value.

Clamp Above—Limits the previous waveform’s output to be above this waveform’s value.

Clamp Below—Limits the previous waveform’s output to be below this waveform’s value.

Characteristic Graph
Characteristic Graph shows one of three displays, controlled by the radio buttons below the display.

This Wave—Shows the current waveform only, independent of all other waveforms.

This Output—Shows the output of the current waveform, including all previous waveforms.

Final Output—Shows the output of all the waveforms in the list. You can also see the final output by turning on the Track View — Curve Editor display for the track which has the waveform controller assigned.

All displays show the output graph of the controller waveforms in a solid dark line, with the zero line drawn in a dotted gray line. Two numeric displays to the right show the high and low range of the waveform curve. The graph automatically scales vertically to fit the waveform output curve, and scales horizontally to two times the period of the longest-period waveform.

XRef Controller

This controller lets you externally reference any type of Transform controller (page 2–298) from another scene file. The XRef controller follows the same concepts and principles as the XRef objects (page 3–394) and XRef material (page 2–1616); it can improve upon the collaborative synergy within a production environment by letting you access animation data currently in another scene while someone else updates it. For example, while an animator works locally on a character’s walk cycle, a scene integrator can externally reference it into his master scene comprised of several characters. The integrator can now regularly update his master scene with the latest changes from the source scene; if he notices a problem, the animator can make the appropriate modifications, which reflect in the master scene.
You can create an XRef controller with or without an XRef object:

- You can externally reference a source object’s animation without the object itself by assigning an XRef controller to your current selection (page 2–384).
- You can create an XRef object, which automatically nests the source object’s Transform controller in an XRef controller. The XRef Objects dialog’s XRef Entities list (page 3–402) lists both XRefs as separate entries.

Note: The Merge Transforms option must be off to externally reference a controller; otherwise, the controller merges with the current scene.

To remove an XRef controller, you can either right-click the entry in the XRef Entities list and choose Merge in Scene from the contextual menu, or assign a new Transform controller to your object.

Note: Replacing the XRef controller with another type removes any animation it contains.

Although XRef controllers are read-only in your master scene, you can add a local offset to the object’s animation (page 2–385).

Procedures

To assign an XRef controller using the Motion Panel:

1. Select an object in the current screen.
2. On the Motion Panel, click Parameters, and open the Assign Controller rollout.
3. Highlight the Transform track in the Assign Controller list.
4. Click the Assign Controller button, and then select XRef Controller from the Assign Transform Controller dialog.
5. In the Open File dialog, navigate to the file from which to externally reference the transform controller and then click Open.
6. Use the XRef Merge dialog to designate the object whole transform controller you want to XReference.

The software references the scene object’s transform controllers from the external object’s controllers.

Tip: You can also XReference a different controller from either another file or another object via the Parameters rollout of the XRef controller.
To add and reset a Transform offset to an XRef Object’s Animation

1. Create a sphere at [0,0,0] and animate it from [0,0,0] to [5,5,5]
2. Save your scene, then choose File > Reset.
3. Choose File > XRef Objects.
4. In the XRef Objects dialog, make sure Merge Transforms is off, then click the Create XRef Record From File and select the scene you just saved.
   The sphere appears in your master scene at [0,0,0].
5. Move the sphere to [10,10,10].
   The sphere now translates from [10,10,10] to [15,15,15].
6. Right-click the XRef Controller entry in the XRef Entities list of the XRef Objects dialog.
7. From the contextual menu, choose Reset PRS Offset.
   This removes the sphere’s local offset, which now returns to its original [0,0,0] position.

Interface

These controls, similar to those on the XRef Object rollout (page 3–414), let you change the file path, file name, and object name of the source of the XRef controller.

 Highlight corresponding XRef Record in the XRef Object dialog—Opens the XRef Objects dialog (page 3–397) and highlights the corresponding XRef record within.

File Name controls

File Name field—Displays the path and file name of the scene containing the source controller. You can edit this to point to a different path and file.

File Name display—Displays the file name only, without the path.

Path button—Opens a file dialog from which you select a new file (either .max or .chr).

Object controls

Object Name field—Displays the name of the source object pointed to in the source file which holds the source controller.
Object Name display—Displays the file name of the source object.

Path button—Opens an XRef Merge dialog (page 3–406) pointing to the scene in the XRef File Name field. Here, you can specify a different object to be used as the XRef object.

status line—Displays status information regarding the XRef controller:
- “Unresolved XRef, File Not Found”: Cannot find the scene file containing the specified object name.
- “Unresolved XRef, Object Not Found”: Cannot find the object in the specified scene.
- “XRef Resolved”: Both scene and object match.

Controller Subdialogs

Audio Controller Dialog

Track View or Motion panel > Highlight a track using the Audio controller in the Track View hierarchy. > Right-click the track. > Properties

Track View or Motion panel > Double-click a track using the Audio controller in the Track View hierarchy. > Properties

Adding a sound track to your animation allows you to synchronize animation to sound. Add a sound track to lip-sync a character speaking, for example.

Interface

Audio File group

Use this group to add and remove sound files from the controller, and to adjust amplitude.

Choose Sound—Displays a standard file selector dialog. You can choose WAV and AVI files.

Remove Sound—Removes any sound file associated with a controller.

Absolute Value—Controls the interpretation of sound amplitude. The value returned by the Audio controller is sample amplitude divided by maximum amplitude.

Value=(sample amp.)/(maximum amp.)

When Absolute Value is turned on, the maximum amplitude equals the maximum sampled amplitude from the waveform. This ensures that potential for the output value reaches the target value.

When off, the maximum amplitude equals the maximum potential amplitude of the waveform. Output reaches the target value only if the waveform reaches its maximum potential amplitude.
The maximum potential amplitude for an 8-bit file is 128; for a 16-bit file, it’s 32768.

**Real Time Control group**

Use this group to create interactive animation that’s driven by sound captured from an external audio source, such as a microphone. Use these options only for interactive presentations. You can’t save the real-time sound or save the animation produced by the controller.

**Enable Real Time Device**—Sets whether sound is captured from an external audio source. This option is inactive if a sound capture device is not installed in your system.

- When on, any selected audio file is ignored, and the controller uses sound captured by the selected device.
- When off, the controller uses the selected audio file.

**Real Time device list**—Displays all available real-time sound devices installed in your system. Select the device you want to use for real-time sound capture.

**Sample group**

This group contains controls to filter out background noise, smooth out the waveform, and control display in Track View.

**Threshold**—Sets the bottom cut-out level as a percentage of total amplitude. Any amplitude below the threshold drops to 0.0.

- Threshold range is from 0.0 to 1.0.
- A Threshold of 0.0 has no effect on amplitude output values.
- A Threshold of 1.0 drops all amplitude output values to 0.0.

You can use low threshold values to filter out background noise from the controller.

**Oversampling**—Smooths the waveform. Multiple samples are averaged to remove peaks and valleys. Enter a number in the Oversampling field to calculate the average.

**Fast Track View**—Controls the display of oversampling.

- When turned on, oversampling is ignored for the Track View display.
- When turned off, oversampling is applied to the Track View display. High oversampling values can slow the display of the waveform.

**Base & Target Scale groups**

Here you enter minimum and maximum parameter values returned by the controller. The fields you see vary by the type of parameter using the Audio controller.

- Float parameters are displayed in the Controller Range group with Min. and Max. fields.
- Vector parameters (3 components), such as Transforms, display Base and Target groups with fields for X, Y, and Z values.

**Base Scale**—Defines the float value or X, Y, and Z values returned for an amplitude of 0.0.

**Target Scale**—Defines the float value or X, Y, and Z values returned for maximum amplitude.

**Channel group**

With this group you select which channel drives the controller output value. These options are only available if you have chosen a stereo sound file.

**Left**—Uses the left channel amplitude.

**Right**—Uses the right channel amplitude.

**Mix**—Combines the two channels so that the returned amplitude is the greater value of either channel.
Attach Controls Dialog (Block Controller)

- Track View > Global Tracks > Block Control > Click and then right-click MasterBlock track. > Properties > Load > Choose a file. > OK > Attach Controls dialog
- Track View > Global Tracks > Block Control > Double-click MasterBlock track. > Properties > Load > Choose a file. > OK > Attach Controls dialog

This dialog is displayed when you click Load in the Master Block Parameters dialog (page 2–390). Tracks in blocks previously saved can be mapped to tracks in the current scene.

The Incoming Controls list on the left contains all the incoming tracks. The Copy To list on the right contains all the tracks in the current scene that you will attach to.

Interface

Add—Select tracks in the current scene in the Track View Pick dialog (page 2–392).
Add Null—Allows a space to be taken if you don’t want to use a particular track.
Match by Node—Select tracks on the left that you want to match. Click Match By Node. Then select a group of tracks that you want to match to. The system attempts to match the controls based on their names.
Delete—Deletes a track from the list.
Move Up, Move Down—Move tracks up and down to align them before attaching them.
OK—Imports the tracks and closes the dialog.
Cancel—Cancels the Load operation.

Barycentric Morph Controller Key Info Dialog

Select a Morph object > Track View - Dope Sheet > Right-click a morph key. > Barycentric Morph Controller Key Info dialog

You can change morph target weighting using controls in the Barycentric Morph Controller Key Info dialog.
**Interface**

**Current Key**—Specifies the current key that you’re adjusting.

**Time**—Specifies where, in time, the current key is placed.

**Tension/Continuity/Bias**—Adjusts the TCB parameters of the key spline interpolation.

**TCB Spline**—Displays the key interpolation spline.

**Targets**—Lists all morph targets for the object, along with the percentage of their influence at the current key. The total percentage of all targets is displayed below the window. You can select any target in this window, and then adjust its percentage of influence using the spinner at right.

**Percentage**—Sets the percentage of influence for the target selected in the list window. Percentage values can be negative as well as greater than 100 percent.

**Constrain to 100%**—Limits total weight of all targets to 100 percent. As you increase or decrease the percentage of a selected target, the other targets adjust accordingly. The adjustment takes the form of balancing all of the target percentages so that their relative weights remain the same.

When this check box is turned off, you can adjust the weight of each target without affecting the others, and create a total that’s greater or less than 100 percent. Totals greater than 100 percent cause the morph object to scale up in size, while totals less than 100 percent cause the morph object to scale down. Note that this check box is global, and not confined to a single key or track.

---

**Block Parameters Dialog (Block Controller)**

After clicking Add in the Master Block Parameter dialog and selecting tracks in the Track View Pick dialog to create a Block, clicking OK in the Track View Pick dialog displays the Block Parameters dialog.
Interface

Name Field—Names the block.

Start, End—Set the range of the block in frames.

Color—Selects a color for the Block. Displays a color selection dialog.

OK—Saves the parameters and closes the dialog.

Cancel—Closes the dialog without saving the parameters.

Master Block Parameters Dialog (Block Controller)

Add—Displays the Track View Pick dialog. In the Track View Pick dialog, select tracks to include in a Block. Valid tracks are displayed in darker text.

Add Selected—Creates a block using the tracks already selected in the Track View hierarchy. Any invalid tracks are ignored.

Select the tracks (include the Master Block track), and then right-click Master Block in the Track View hierarchy.

Replace—Replaces the currently selected block.

Remove—Remove the selected block from the list.

Load—Loads a block from disk. Displays the Attach Controls dialog.

Map incoming tracks to tracks in your scene using controls in the Attach Controls dialog.

Save—Saves the current block to disk.

After assigning a Master Block, right-click the Master Block track to display the Master Block Parameters dialog (page 2–390). This is the first step in creating a block.
Master Track Key Info Dialog (Master Point Controller)

With Track View in Dope Sheet mode, right-click a green master key of a Master Point controller (page 2–346) to display the Master Track Key Info dialog.

**Interface**

[key arrows]—Moves to the next or previous key.

Time—Moves the master key to a different frame or time.

Sub Keys list window—Displays all the animated sub-object keys at a particular frame or time.

Select Point—Select a node in the List Window and the corresponding node in the viewports is selected, if the corresponding sub-object level is active.

Key Frame Properties—Displays and lets you adjust interpolation and position. See Bezier Controller (page 2–310).

Slave Parameters Dialog (Block Controller)

Every time you create a block, all tracks within the block are assigned a Slave controller, which allows the Master Block to transfer key data.

The Slave controller can be assigned without being connected to a Master Block controller. Controls in the Slave Parameters dialog allow you to attach the slave to a master. If the slave is not attached to a master, a dialog is displayed listing the available master controls you can attach to. The Track View Pick dialog (page 2–392) is displayed, listing the tracks you can add.

Right-click a Slave controller in the Track View hierarchy to display the Slave Parameters dialog. The list window displays any assigned tracks.
### Interface

#### Slave Parameters

- **Sphere01/X Position**
- **Add New Link**
- **Remove Link**
- **Collapse Control**

**Add New Link**—Adds a link. Displays the Add New Link dialog with available tracks. Click a track and then click OK.

**Remove Link**—Removes the highlighted link.

**Collapse Control**—Collapses the Slave controller to a standard controller. Existing keys are copied to the new controller.

**OK**—Closes the dialog.

#### Track View Pick Dialog (Block Controller)

This dialog is displayed when track selection is necessary, by clicking Add in the Master Block Parameters dialog (page 2–390), for example.

Select tracks in the dialog that you want to include in a Block. Valid tracks are darker.

#### Interface

**Cancel**—Exits the Track View Pick dialog with no changes.

If tracks are highlighted in the Hierarchy list, then the Block Parameters dialog (page 2–389) is displayed when you click OK, to allow you to set the duration for the Block.

### Animation Constraints

An animation constraint is a special type of controller that can help you automate the animation process. You can use constraints to control an object’s position, rotation, or scale through a binding relationship with another object.

A constraint requires an animated object and at least one target object. The target imposes specific animation limits on the constrained object.
For example, to quickly animate an airplane flying along a predefined path, you can use a Path constraint to restrict the airplane’s motion to a spline.

You can use keyframe animation to toggle the constraint’s binding relationship with its targets over a period of time.

Common uses for constraints include:

- Linking one object to another over a period of time, such as a character’s hand picking up a baseball bat
- Linking an object’s position or rotation to one or several objects
- Keeping an object’s position between two or more objects
- Constraining an object along a path or between multiple paths
- Constraining an object to a surface
- Making an object point toward another object
- Keeping an object’s orientation in relation to another

There are seven types of constraints:

- Attachment constraint attaches an object’s position to a face on another object
- Surface constraint restricts an object’s position along the surface of another object
- Path constraint restricts an object’s movement along a path
- Position constraint causes the constrained object to follow the position of another object
- Link constraint links the constrained object from one object to another
- LookAt constraint constrains an object’s orientation so that it’s always looking at another object

- Orientation constraint causes the rotation of the constrained object to follow the rotation of another object

Tip: You can use Schematic View to see all the Constraint relationships in a scene.

**Using Constraints with Bones**

Constraints can be applied to bones as long as an IK controller is not controlling the bones. If the bones have an assigned IK controller, you can only constrain the root of the hierarchy or chain.

**Attachment Constraint**

Animation menu > Constraints > Attachment Constraint

The Attachment constraint is a position constraint that attaches an object’s position to a face on another object (the target object doesn't have to be a mesh, but must be convertible to a mesh).

By keying different attachments over time, you can animate the position of an object over the irregular surface of another object, even if that surface is changing over time.
Procedures

Example: To attach a cone to a bending cylinder:
1. In the Perspective viewport, create a cylinder with a radius of 20, a height of 30, and 10 height segments.
2. In the Perspective viewport, create a cone with a radius 1 of 15, a radius 2 of 5, and a height of 30.
3. Select the cylinder, apply a Bend modifier, and set the bend angle to -70 degrees.
4. Turn on Auto Key, move to frame 100, and set the bend angle to 70 degrees.
   The cylinder bends from one direction to the other over 100 frames.
5. Turn off Auto Key.

Example continued: To adjust the position of the cone relative to the face:
1. Drag in the face display window to position the red x relative to the triangle representing the face. (Because of the radial arrangement of cap faces in a cylinder, the upper-left corner of the displayed triangle is the center of the cylinder cap. You can turn off Edges Only for the cylinder to see this.)
2. Adjust the A and B spinners to move the cone across the surface of the face.

Example continued: To assign the Attachment constraint and adjust the cone:
1. Select the cone.
2. On the Motion panel, open the Assign Controller rollout, click the Position track, click Assign Controller, and choose Attachment.
   The cone moves to the origin of the scene, and the Attachment Parameters rollout is displayed.
3. Click the Pick object, and then click the cylinder.
   The name of the cylinder is displayed above the Pick Object button.
   Go to frame 0. Arc Rotate the Perspective viewport so you can see the top surface of the cylinder.
4. Click Set Position, and click and drag over the faces on the top surface of the cylinder.
   The cone jumps to the top of the cylinder. As you drag the mouse, it jumps to whichever face you drag over.
5. Release the mouse when the cone is on the top surface of the cylinder.

Interface

Parameters for this constraint are available on the Motion panel after the controller has been assigned.
Object Name text—Specifies the target object to which the source object is attached.

Pick Object—Selects and picks the target object in the viewports for the attachment.

Align to Surface—Fixes the orientation of the attached object to the face where it’s assigned. When this is turned off, the orientation of the attached object is not affected by the orientation of the face on the target object.

Update group

Update—Updates the display.

Manual Update—Enables Update.

Key Info group

Current Key—Displays the current key number and lets you move to another key.

Time—Displays the current frame, and lets you move the current key to a different frame.

Position group

Face—Provides the index of the face to which the object is attached. Range=0 to 268435455.

A/B—Contains the barycentric coordinates defining the position of the attached object on the face. Range=−999,999 to 999,999.

(display window)—Shows the position of the source object within the attachment face. You can drag within this window to adjust the position of the object relative to the face.

Set Position—Adjusts the placement of the source object on the target object. Drag over the target object to specify a face and a position within the face. The source object moves accordingly over the target object.
TCB group

All of the items in this group are the same as in other TCB controllers (page 2–377). The orientation of the source object is also interpolated and affected by these settings.

- **Tension**—Range=0 to 50
- **Continuity**—Range=0 to 50
- **Bias**—Range=0 to 50
- **Ease To**—Range=0 to 50
- **Ease From**—Range=0 to 50

---

**Surface Constraint**

- **Animation menu > Constraints > Surface Constraint**
- **Animation menu > Track View > New/Open Track View**
  - Select a position track in Track View Hierarchy.
  - Track View toolbar > Assign Controller > Surface

*Surface constraints position the weather symbols on the globe.*

The Surface constraint positions an object along the surface of another object.

The type of object that can be used as the surface object is limited to those whose surfaces can be represented parametrically. Use the Surface constraint with the following types of objects:

- Sphere
- Cone
- Cylinder
- Torus
- Quad Patches (single quad patches)
- Loft object
- NURBS object

The surface used is a "virtual" parametric surface, and not the actual mesh surface. Objects with a low number of segments might have a mesh surface quite different than the parametric surface.

The parametric surface ignores Slice and Hemisphere options. So if the object is sliced, for
example, the controlled object will position itself as if the missing portion were still there.

Since the Surface constraint only works on parametric surfaces, if you apply a modifier that converts the object to a mesh, the constraint will no longer work. For example, you can’t use it with a cylinder with a bend modifier applied.

Procedure
Example: To animate a sphere over the surface of a cylinder:

1. In the Top viewport, create a cylinder and a sphere.
2. Select the sphere, open the Motion panel, expand the Assign Controller rollout, and then expand the Transform heading in the list.
3. In the list window, click the Position item and then click Assign Controller.
4. In the Assign Position Controller dialog, choose Surface and then click OK.
   The Surface Controller Parameters rollout replaces the Key Info rollout.
5. Click Pick Surface, and then select the cylinder.
6. Turn on Auto Key, and place the time slider at frame 0.
7. Use the V Position spinner to move the sphere to a starting position at the bottom of the cylinder.
8. Place the time slider at frame 100.
9. Use the V Position spinner to place the sphere at the top of the cylinder.
10. Set U Position to 300.
   Turn off Auto Key and play the animation. The sphere moves over the surface of the cylinder in a helical path.

Interface
The Surface Constraint Parameters rollout is on the Motion panel.

Current Surface Object group
This group provides a method for selecting and then displaying the selected surface object.

Text—Displays the name of the selected object.

Pick Surface—Selects the object you want used as a surface.

Surface Options group
This group provides controls for adjusting the position and orientation of the object along the surface.

U Position—Adjusts the position of the controlled object along the U coordinates of the surface object.

V Position—Adjusts the position of the controlled object along the V coordinates of the surface object.

No Alignment—When on, the controlled object is not reoriented, regardless of its position on the surface object.
**Align to U**—Aligns the local Z axis of the controlled object with the surface normal of the surface object, and the X axis with the U axis of the surface object.

**Align to V**—Aligns the local Z axis of the controlled object with the surface normal of the surface object, and the X axis is aligned with the V axis of the surface object.

**Flip**—Flips the alignment of the local Z axis of the controlled object. This check box is not available if No Alignment is turned on.

---

**Path Constraint**

*Animation menu > Constraints > Path Constraint*

Path constraint positions the service platform along the side of the bridge.

A path constraint restricts an object’s movement along a spline or at an averaged distance between multiple splines.

A path target can be any type of spline. The spline curve (target) defines a path of motion for the constrained object. Targets can be animated using any of the standard translation, rotation, scale tools. Setting keys on the path's sub object level, such as vertex, or segment will animate the path while affecting the constrained object.

---

**Multiple Targets and Weighting**

A constrained object can be influenced by several target objects. When using multiple targets, each target has a weight value that defines the degree by which it influences the constrained object, relative to other targets.

Using Weight is meaningful (and available) only with multiple targets. A value of 0 means the target has no influence. Any value greater than 0 causes the target to influence the constrained object relative to other targets’ Weight settings. For example, a target with a Weight value of 80 will have twice the influence of a target with a Weight value of 40.

**Procedures**

To assign a Path constraint:

1. Create a Sphere with a radius of **10** and a Circle with a radius of **60**.
2. With the Sphere selected, choose Animation menu > Constraints > Path Constraint.
   
   You are now in select target mode.
3. In the viewport, select the Circle shape.

To access the Path constraint’s parameters through the Motion panel:

1. Select the Sphere.
2. Open the Motion panel.
3. In the PRS Parameters rollout, click the Position button.
   
   The Path constraint’s settings are located in the Path Parameters rollout.

To assign a Path constraint through the Motion panel:

1. Create a Sphere with a radius of **10** and a Circle with a radius of **60**.
2. Select the Sphere.
3. On the Motion panel and click Parameters.
4. Open the Assign Controller rollout and select the Position controller.
5. Click the Assign Controller button.
6. Choose Path Constraint from the Assign Position Controller dialog.
7. On the Motion panel, click Parameters.
8. In the Path Parameters rollout, click Add Path.
9. In the viewport, select the Circle.

To edit weight values:
1. Open the Create > Shapes panel and create a Line that is about 120 units long.
   Tip: Use the diameter of the Circle to gauge the length of the Line.
2. Select the Sphere.
3. On the Motion panel, open the Path Parameters rollout.
4. Click the Add Path button and select the line.
   The Sphere is now affected equally by both paths since the path weighting defaults to 50
5. Adjust the Weight spinner or enter a numerical value for the weight value.

To animate weight values:
1. Select the Sphere.
2. On the Motion panel, open the Path Parameters rollout.
3. Turn on the Auto Key button.
4. Select the Line01 from the Path list.
5. Place the time slider at frame 50 and change the Weight of Line01 to 75.
6. Move the time slider at frame 100 and change the Weight of Line01 to 10.
7. Select the Circle01 path and change its Weighting to 25.
8. Turn off Auto Key and play the animation.

To correct path constrained object flipping:
When an object is assigned a path constraint and the follow box is turned on, the object will rotate as it moves along the path. Sometimes the object is subject to unwanted flipping.
1. Select the object that is flipping.
2. On the Animation menu choose Constraints > Orientation constraint, then constrain the object to another object’s orientation.
3. Use the control object to adjust the flipping. Animate the orientation of the control object, while watching the flipped object at the problematic frames.
Once you assign a Path constraint, you can access its properties on the Path Parameters rollout in the Motion panel. In this rollout you can add or delete targets, assign weighting, and animate each target’s weight value.

**Note:** When you assign a Path constraint via the Animation menu, the software assigns a Position List controller to your object. In the Position List rollout list you will find Path Constraint. This is the actual path constraint controller. To view the Path Parameters rollout with the constraint settings, double-click Path Constraint in the list.

**Add Path**—Adds a new spline path that influences the constrained object.

**Delete path**—Removes a path from the target list. Once removing the path target, it will no longer influence the constrained object.

**Weight**—Assigns and animates weight values for each target.

**% Along Path**—Sets the percent that the object is positioned along the path. This duplicates the Value spinner in the track Properties dialog for the Percent track in Track View. If you want to set keys to place an object at a certain percent along the path, turn on Auto Key, move to the frame where you want the key set, and adjust the % Along Path spinner to move the object.

**Note:** The % Along Path value is based on the parameterization of the spline path’s U value. A NURBS curve might not have an evenly spaced U value, so a value of 50 % Along Path might not translate visually to 50 per cent of the NURBS curve’s length.

**Follow**—Aligns the object to the trajectory as it follows the contour.

**Bank**—Allows the object to bank (roll) as it negotiates the curves of the spline.

**Bank Amount**—Adjusts the amount of the banking to one side or the other, depending on whether the value is positive or negative.

**Smoothness**—Controls how rapidly the roll angle changes as the object moves through bends in the trajectory. Smaller values will make the object more responsive to subtle changes in the curve, while larger values smooth out jerking. The default value is a good value for general damping along the curve. Values below 2 tend to make the action jerky, but values around 3 can be very useful for simulating a certain degree of realistic instability.
**Allow Upside Down**—Turn on to avoid the situation in which an object flips when going around a vertically oriented path.

**Constant Velocity**—Provides a constant velocity along the path. When off, the velocity of the object along the path varies depending on the distance between the vertices on the path.

**Loop**—By default, when the constrained object reaches the end of a path it can no longer move past the end point. The loop option changes this behavior so that when the constrained object reaches the end of the path it loops back to the starting point.

**Relative**—Turn on to maintain the original position of the constrained object. The object will follow the path with an offset distance based on its original world space position.

**Axis**—Defines which axis of the object is aligned to the trajectory of the path.

**Flip**—Turn on to flip the direction of the axis.

The following controls are located on the Hierarchy panel while the IK button is active:

- **Active**—Activates an axis (X/Y/Z). Allows the selected object to animate along the activated path.

- **Limited**—Limits the range of motion allowed on an active path. Use in conjunction with the From and To spinners.

- **Ease**—Causes a joint to resist motion as it approaches its From and To limits. Simulates an organic joint, or worn mechanical joint, moving or rotating freely in the middle of its range of motion but moving less freely at the extremes of its range.

- **From and To Spinners**—Determine for path limits. Use in conjunction with the Limited function.

- **Damping**—Applies resistance over a joint’s motion along the path. Simulates the natural effect of joint friction or inertia.

---

**Position Constraint**

*Animation menu > Constraints > Position Constraint*

Position constraints align the elements of the robot assembly.

A position constraint causes an object to follow the position of an object or the weighted average position of several objects.

In order to activate, a position constraint requires an object and a target object. Once assigned the object becomes constrained to the target object’s position. Animating the target’s position causes the constrained object to follow.

Each target has a weight value defining its influence. A value of 0 is equal to off. Any value greater than 0 will cause the target to influence the constrained object. Weight values can be animated to create effects such as a ball being picked up from a table.
Multiple Targets and Weighting

A constrained object can be influenced by several target objects. When using multiple targets, each target has a weight value that defines the degree by which it influences the constrained object, relative to other targets.

Using Weight is meaningful (and available) only with multiple targets. A value of 0 means the target has no influence. Any value greater than 0 causes the target to influence the constrained object relative to other targets’ Weight settings. For example, a target with a Weight value of 80 will have twice the influence of a target with a Weight value of 40.

For example, if a sphere is Position-constrained between two targets and each target’s weight value is 100, the sphere will maintain an equal distance between both targets even when they are in motion. If one of the weight values is 0 and the other is 50, then the sphere is influenced only by the target with the higher value.

Procedures

To assign a Position constraint:
1. Select the object you want to constrain.
2. Choose Animation menu > Constraints > Position Constraint.
3. Select the target object.

To access the Position constraint’s parameters through the Motion panel:
1. Select the Position-constrained object.
2. On the Motion panel, on the Position list, double-click Position Constraint.
   The Position constraint parameters are located under the Position Constraint rollout.

To edit weight values:
1. Select the constrained object.
2. On the Motion panel, on the Position list, double-click Position Constraint.
   The Position constraint parameters are located under the Position Constraint rollout.
3. Click a target from the list.
4. Adjust the Weight spinner or enter a numerical value for the weight value.

To animate weight values:
1. Select the constrained object.
2. On the Motion panel, on the Position list, double-click Position Constraint.
   The Position constraint parameters are located under the Position Constraint rollout.
3. Click a target from the list.
4. Turn on the Auto Key button.
5. Adjust the Weight spinner or enter a numerical value for the weight value.

Example: To assign a Position constraint with two targets and editing weights:
1. In the Top viewport, create a sphere, a box, and a cylinder so that the box is between the sphere and the cylinder.
2. Click to select the box, assign a Position constraint, and select the sphere as the target.
3. Click to select the box, assign a Position constraint, and select the cylinder as the target.
   The box is now position-constrained between the two targets.
4. In the Top viewport, move the sphere around. As the sphere moves, the box maintains an equal distance between the sphere and the cylinder. This is because the weight values for both targets are equal. By default the values are 1.00. If the sphere had a higher weight value than the cylinder, the sphere would influence the box more than the cylinder.
5. To edit the weight values, select the box.

6. Open the Motion panel and view the Position Constraint rollout.

7. Click the Cylinder’s name in list of targets.

8. Using the Weight spinner, change the value from 50 to 20.
   As the value decreases, the box moves closer to the sphere.

9. In the Top viewport, select the cylinder and move it around.

10. In the Top viewport, select the sphere and move it around.
    The sphere has more influence over the box’s movement than the cylinder.

Interface

<table>
<thead>
<tr>
<th>Add Position Target</th>
<th>Delete Position Target</th>
</tr>
</thead>
<tbody>
<tr>
<td>Target</td>
<td>Weight</td>
</tr>
<tr>
<td>Circle01</td>
<td>50</td>
</tr>
<tr>
<td>Cylinder01</td>
<td>50</td>
</tr>
</tbody>
</table>

Once you assign a Position constraint, you can access its properties on the Position Constraint rollout in the Motion panel. In this rollout you can add or delete targets, assign weighting, and animate each target’s weight value.

Note: When you assign a Position constraint via the Animation menu, the software assigns a Position List controller to your object. In the Position List rollout list you will find Position Constraint. This is the actual Position Constraint controller. To view the Position Constraint rollout, double-click Position Constraint in the list.

**Add position target**—Adds new target objects that influence the position constrained object.

**Delete position target**—Removes targets. Once a target is removed, it will no longer influence the constrained object.

**Weight**—Assigns and animates weight values for each target.

**Keep Initial Offset**—Use Keep Initial Offset to preserve the original distance between the constrained object and the target object. This prevents the constrained object from snapping to the target object’s pivot. The default is Off.

### Link Constraint

Animation menu > Constraints > Link Constraint

A link constraint enables the robot arms to pass a ball.

A Link constraint is used to animate an object linking from one target object to another.

The Link constraint causes an object to inherit the position, rotation, and scale of its target object.
An example of using a link constraint is to pass a ball from one hand to another. Assume that at frame 0 the ball is in the right hand. The hands are animated to meet at frame 50, where the ball is passed to the left hand, and then spread apart until frame 100.

**Procedures**

**Example: To assign a Link constraint:**

1. In the Top viewport, create a sphere and a box.
2. Select the sphere.
3. Open the Motion panel.
4. Expand > Assign Controller rollout.
5. Select the Transform: Position/Rotation/Scale controller.
6. Click Assign Controller.
7. Choose Link Constraint.

It is recommended that you add a Link To World before linking to any target objects. This will allow you to animate the object on its own, before the first link to a target object takes place.

You can also assign Link Constraints through the Animation > Constraints submenu.

**To access the Link constraint’s parameters through the Motion panel:**

1. Select the Link-constrained object.
2. Choose Motion panel > Link Params rollout.

**Example: To assign the Link constraint and animate links:**

1. Move the time slider to frame 0.
2. In the Top viewport, create a sphere, a cylinder and a box.
3. Select the sphere.
4. Open the Motion panel.
5. Expand the Assign Controller rollout.
7. Click Assign Controller.
8. Choose Link Constraint.
9. In the Link Params rollout, click Link To World.
10. Move the time slider to frame 1.
11. Click Add Link and select the cylinder.

It now becomes a target. The Link Constraint relationship is now active between the sphere and the cylinder.

12. Move the time slider to frame 50.
13. Turn on the Auto Key button and move the cylinder a good distance away from where it is.
14. Play back the animation.

The sphere follows the cylinder as it moves. The sphere is link-constrained.

15. Select the sphere.
16. Move the time slider to frame 25.
17. On the Motion panel > Link Param rollout, click Add link and select the box.

You have now added another target that becomes active at frame 25.

18. Turn off the Auto Key button and play back the animation. The sphere is linked to the cylinder from frame 0 to 24. It follows the cylinder until frame 25 where it links to the box.
Once you assign a Link constraint, you can access its properties on the Link Params rollout in the Motion panel. In this rollout you can add and delete targets and animate the time at which each target becomes the active parent of the constrained object.

Add Link—Adds a new link target.

Link to World—Links the object to the world (the scene as a whole). We recommend this be the first target in the list. This prevents the object from reverting to its independent creation or animation transforms if other targets are deleted from the list.

Delete Link—Removes a link target. Once a link target is removed, it will no longer influence the constrained object.

Start Time—The start time spinner is used to assign or edit the frame value of a target. Select one of the target object names in the list window and see the frame where the object becomes a parent. You can adjust the value to change when the link transfer takes place.

Key Mode group

Note: The options Key Nodes and Key Entire Hierarchy have no effect unless the object you are constraining is already part of a hierarchy. If you add objects to the hierarchy after you apply the Link constraint, you have to reapply the Link constraint using the key options you desire.

No Key—When used, no keyframes are written to the constrained object or its targets. The link control happens without inserting any keys. This is similar to how the Link Controller worked in 3ds Max 3.1 and earlier versions.

Key Nodes—When used, keyframes are written to the specified option. There are two options: Child and Parents. Child sets a keyframe only on the constrained object. Parents sets keyframes for the constrained object, its targets, and their upper hierarchy.

Key Entire Hierarchy—Sets keyframes up the hierarchy for the specified option. There are two options: Child and Parents. Child sets a keyframe only on the constrained object and its parents. Parents sets keyframes for the constrained object, its targets, and their upper hierarchy.
LookAt Constraint

Animation menu > Constraints > LookAt Constraint

LookAt constraints enable the antenna dishes to track the satellite.

The LookAt constraint controls an object’s orientation so that it’s always looking at another object. It locks an object’s rotation so that one of its axes points toward the target object. The LookAt axis points toward the target, while the Upnode axis defines which axis points upward. If the two coincide, a flipping behavior may result. This is similar to pointing a target camera straight up.

An example of a LookAt constraint’s use would be to constrain the eyeballs of a character to a point helper. The eyes will then always be aimed at the point helper. Animate the point helper, and the eyes follow. Even if you rotate the character’s head, the eyes maintain their lock on the point helper.

Multiple Targets and Weighting

A constrained object can be influenced by several target objects. When using multiple targets, each target has a weight value that defines the degree by which it influences the constrained object, relative to other targets.

Using Weight is meaningful (and available) only with multiple targets. A value of 0 means the target has no influence. Any value greater than 0 causes the target to influence the constrained object relative to other targets’ Weight settings. For example, a target with a Weight value of 80 will have twice the influence of a target with a Weight value of 40.

Procedures

To assign a LookAt constraint:

1. Select the object you want to constrain. This is the object that will be always looking at its target.
2. Choose Animation menu > Constraints > LookAt Constraint.
3. Select the target object.

To access the LookAt constraint’s parameters through the Motion panel:

1. Select the LookAt Constrained object.
2. On the Motion panel > Rotation list, double-click LookAt Constraint.
   The LookAt constraint parameters are located under the LookAt Constraint rollout.

To edit weight values:

1. Select the constrained object.
2. On the Motion panel > Rotation list, double-click LookAt Constraint.
   The LookAt constraint parameters are located under the LookAt Constraint rollout.
3. Click a target from the list.
4. Use the Weight spinner or enter a numerical value to adjust the weight value.

To animate weight values:

1. Select the constrained object.
2. On the Motion panel > Rotation list, double-click LookAt Constraint.
   The LookAt constraint parameters are located under the LookAt Constraint rollout.
3. Click a target from the list.
4. Turn on the Auto Key button.
5. Use the Weight spinner or enter a numerical value to adjust the weight value.

**Interface**

Once you assign a LookAt constraint, you can access its properties on the LookAt Constraint rollout on the Motion panel. On this rollout, you can add or delete targets, assign weighting, assign
and animate target weight values, and adjust other related parameters.

**Note:** When you assign a LookAt constraint via the Animation menu, 3ds Max assigns a Rotation List controller to your object. In the list on the Rotation List rollout, you will find LookAt Constraint, which is the constraint you assigned. To view the LookAt Constraint rollout, double-click the LookAt Constraint entry in the list.

**Add LookAt Target**—Use to add new targets that influence the constrained object.

**Delete LookAt Target**—Use to remove target objects that influence the constrained object.

**Weight**—Use to assign and animate weight values for each target. Available only when multiple targets are used.

**Keep Initial Offset**—Maintains the constrained object’s original orientation as an offset to its constrained orientation.

**Viewline Length**—Defines the length of the main viewline drawn from the pivot of the constrained object to the pivot of its target (or the average, in case of multiple targets). A negative value draws the line from the constrained object in the opposite direction of the target or targets.

With a single target, the length of the viewline is determined by the distance between the constrained object and the target, as well as the Viewline Length setting. However, if Viewline Length Absolute is on, the distance between the two has no effect on the length.

The color of the viewline is defined by the Target Line element in the Gizmos category of the Colors panel (page 3–799) in the Customize > Customize User Interface dialog (page 3–792).

**Note:** When multiple targets are assigned, additional viewlines drawn from the constrained object to each target object inherit the color of the respective targets. If Viewline Length Absolute is on, the length of each target-specific line is determined by its target’s Weight setting and the Viewline Length value. If Viewline Length Absolute is off, the length of each line is determined by the distance between the constrained object and the respective target, as well as the Viewline Length value. An additional (main) viewline, whose length and color are determined as specified above, indicates the actual, calculated orientation.

**Viewline Length Absolute**—When on, the software uses only the Viewline Length setting for the length of the main viewline; the distance between the constrained object and the target(s) has no effect.

**Set Orientation**—Lets you define the offset orientation of the constrained object manually. When on, you can use the Rotation tool to set the constrained object’s orientation. This orientation is then maintained as the constrained object looks at its target.

**Reset Orientation**—Sets the orientation of the constrained object back to the default. This is useful if you want to reset the constrained object’s orientation after having set the orientation manually.

**Select LookAt Axis**—Use to define the axis that looks at the target. The X,Y,Z check boxes reflect the constrained object’s local coordinate system. The Flip check box reverses the directions of the local axes.

**Select Upnode**—The default Upnode is the World. Turn off World to manually select an object that defines the Upnode plane. This plane is drawn from the constrained object to the Upnode object. If the LookAt Axis and the Upnode axis coincide, the constrained object will flip. Animating the position of the upnode object will move the upnode plane.
Upnode Control group:

Lets you quickly flip between LookAt Upnode Control and Axis Alignment.

**LookAt**—When selected the Upnode matches the LookAt target.

**Axis Alignment**—When this is selected the Upnode Aligns to the object axis. Choose which axis (X, Y or Z) in the Source Upnode Alignment group directly below Upnode Control.

Source/Upnode Alignment group

**Source Axis**—Chooses the constrained object’s axis that is to be aligned to the Upnode Axis. The Source Axis reflects the constrained object’s Local Axis. The Source Axis and LookAt Axis work together therefore the Axis used to define the LookAt Axis will be unavailable.

**Aligned to Upnode Axis**—Chooses the Upnode axis that the selected Source Axis aligns to. Note that the selected Source axis may or may not be able to completely align to the Upnode Axis.

An Orientation constraint causes an object’s orientation to follow the orientation of an object or averaged orientation of several objects.

An Orientation Constrained object can be any rotatable object. When constrained it will inherit its rotation from a target object. Once constrained you can not rotate the object manually. You may move or scale the object as long as its not constrained in a manner that effects the object’s position or scale controller.

The target object can be any type of object. The rotation of a target object drives the constrained object. Targets can be animated using any of the standard translation, rotation, and scale tools.

**Multiple Targets and Weighting**

A constrained object can be influenced by several target objects. When using multiple targets, each target has a weight value that defines the degree by which it influences the constrained object, relative to other targets.

Using Weight is meaningful (and available) only with multiple targets. A value of 0 means the target has no influence. Any value greater than 0 causes the target to influence the constrained object relative to other targets’ Weight settings. For example, a target with a Weight value of 80 will have twice the influence of a target with a Weight value of 40.

**Procedures**

**To assign an Orientation constraint:**

1. Select the object you want to constrain.
2. Choose Animation menu > Constraints > Orientation Constraint.

**To access the Orientation constraint’s parameters through the Motion panel:**

1. Select the Orientation-constrained object.
2. On the Motion panel > Rotation list, double-click Orientation Controller.

   The Orientation constraint parameters are located on the Orientation Constraint rollout.

   **To edit weight values:**
   1. Select the constrained object.
   2. Open the Motion panel > Orientation Constraint rollout.
   3. Click a target from the list.
   4. Use the Weight spinner or enter a numerical value to set the weight value.

   **To animate weight values:**
   1. Select the constrained object.
   2. Open the Motion panel > Orientation Constraint rollout, and choose a target from the list.
   3. Turn on the Auto Key button.
   4. Use the Weight spinner or enter a numerical value to set the weight value.

**Interface**

Once you assign an Orientation constraint, you can access its properties on the Position Constraint rollout in the Motion panel. In this rollout you can add or delete targets, assign weighting, assign and animate target weight values, and adjust other, related parameters.

**Note:** When you assign an Orientation constraint via the Animation menu, the software assigns a Rotation List controller to your object. In the Rotation List rollout list you will find Orientation Constraint, which is the constraint you assigned. To view the Orientation Constraint rollout, double-click Orientation Constraint entry in the list.

**Add Orientation Target**—Adds new target objects that influence the constrained object.

**Add World as Target**—Aligns the constrained object to the world axis. You can weight the amount
of influence that the world target has on the constrained object as you would any other target object.

**Delete Orientation Target**—Remove targets. Once removing the target, it will no longer influence the constrained object.

**Weight**—Assigns and animates weight values for each target.

**Keep Initial Offset**—Preserves the original orientation of the constrained object. When you turn off Keep Initial Offset, the object adjusts itself to match the orientation of its target or targets. Default=off.

**Transform Rule**—When an orientation constraint is applied to an object that is part of a hierarchy, this determines whether the local node transform or the parent transform will be used for the orientation constraint.

- **Local**—When selected, the local node transform is used for the orientation constraint.
- **World**—When selected, the parent or world transform will be applied, rather than the local node transform.

---

**Wire Parameters**

Wire Parameters lets you link parameters from one object to another in the viewport, so that adjusting one parameter changes the other automatically. This enables you to set up one- and two-way connections between specified object parameters, or to control one or more objects with a dummy object containing the desired parameters. By wiring parameters, you can set up custom constraints directly without having to go to Track View and assign controllers.

Parameter wiring is accessible from the Animation menu and the *quad menus* *(page 3–694)*. The Wire Parameters command is available only if a single node is selected. Choosing the Wire Parameters command displays a hierarchical pop-up menu with levels and items corresponding to the animatable tracks that would be visible for that object in Track View.

When you make a parameter selection, a dashed line, similar to that displayed in the *Select and Link mode* *(page 2–422)*, is drawn from the selected object to the mouse cursor. The cursor changes from an arrow to a cross whenever it is over a valid destination object. You can right-click at any time to cancel the parameter wiring.

While the dashed line is displayed, you can click a destination node or on empty space in the viewport to customize the relationship between two wired parameters. If you click empty space, the *Parameter Wiring dialog* *(page 2–412)* opens showing the first parameter in the left Tree View and the full scene in the right tree. Clicking a destination node (which can be the same as the originating node) displays a hierarchical pop-up menu for the destination object so you can choose the destination parameter. After you choose a second parameter, the Parameter Wiring dialog opens.

You can wire one-way and two-way connections between parameters. For one-way wires, one parameter is effectively slaved to the other and its value changes as the controlling parameter changes, according to a user-defined transfer expression. The controlling parameter can be animated and adjusted as needed using all the animation tools in 3ds Max. This includes making it a controlled parameter in another
parameter-wiring setup, so that you could potentially set up a chain of controlled parameters.

For two-way wiring, the software assigns Wire controllers of the appropriate kinds to each of the parameters and they are cross-linked so that changing either parameter cause linked changes in the other.

Note: You should establish all object hierarchies before wiring parameters in a scene. If you change the hierarchy of an object that has a wired parameter, it will take on new parameters, which could introduce undesired results in your wired parameters.

Tip: Use Schematic View (page 3–640) to see all the wired parameter relationships in a scene. You can also use Schematic view to wire parameters.

Procedure
To attach wire parameters:

1. Select the first object you want to use.

2. Choose Animation menu > Wire Parameters > Wire Parameters, or right-click the object and choose Wire Parameters.

A pop-up menu displays the parameters you can link.

Note: Wire Parameters works only with parameters that can be animated. The menu options displayed depend upon the selected object and are the same options you would see for the selected object in Track View.

3. Choose the parameter you want to link to another object from the displayed menu.

A dashed line appears.

4. Move the cursor to the second object you want to use. When the cursor changes from an arrow to a selection cross, you are over a valid destination object. Click to select the destination object.

The Parameter Wiring dialog allows you to define the relationships for Wire Parameters (page 2–411). In this dialog, you can create new one and two-way control relationships between object parameters, edit existing relationships, and create or edit expressions which define the parameter relationships.

Only parameters that can be animated can be wired. Sub-objects, such as vertices, must be animated before they can be wired.

Parameter wires can be used to establish connections from Manipulators (page 2–27).
Parameter Wiring Dialog

and Custom Attributes (page 1–129) to objects, materials, and modifiers.

Note: Parameter Wiring is a modeless dialog (page 3–973), and you can have several dialogs open at the same time.

Procedures

Example: To use an expression with wire parameters:
1. Create a box and a sphere in your scene.
2. Right-click the box, and from the quad menu choose Transform quadrant > Wire Parameters.
3. From the pop-up menu, choose Object (Box) > Length.
   A rubber-band dashed line now connects the box and the mouse cursor.
4. Click the sphere and choose Transform > Position > Z Position from the pop-up menu.
   The position of the sphere and the length of the box are now wired.
5. In the Parameter Wiring dialog, create a one-way wire by clicking the arrow pointing toward the box’s tree view.
6. Type abs( before Z_position, followed by a closing parenthesis, ), in the expression text box for Box01, so that the entire expressions is abs(Z_Position).
7. Click Connect.
8. Move the sphere upward along the Z axis in the viewport.
   Note that as the sphere moves in the viewport, the length of the box changes. Using abs() ensures that the box never has a negative length.

To control several slave parameters from one master parameter:
1. Open the Parameter Wiring dialog.
2. Choose the master parameter in the tree view.
3. Choose the first slave parameter in the other tree view.
4. Click the arrow pointing toward the slave parameter.
5. Enter the desired relationship expression in the expression text box.
6. Click Connect.
7. Keeping the master parameter selected, choose another slave parameter from the tree view.
8. Click the arrow pointing toward the slave parameter.
9. Enter the desired relationship expression in the expression text box.
10. Click Connect.
   You can repeat this cycle to set up as many slaves as you want. The result is a “fan” of parameter wires, so that you can control all of the slave parameters at once as you change the master parameter.

To create a chain of wired parameters:
1. Open the Parameter Wiring dialog.
2. Choose the first controlling parameter in one tree view.
3. Choose the first slave parameter in the other tree view.
4. Click the arrow pointing toward the slave parameter.
5. Enter the desired relationship expression in the expression text box.
6. Click Connect.
7. Keeping the original slave parameter selected, choose the next slave parameter from the tree view.
8. Click the arrow pointing toward the new slave parameter.
9. Enter the desired relationship expression in the expression text box.
10. Click Connect.

You can repeat this cycle, continuing to alternate slaves to masters as many times as you like. The result is a “daisy chain” of parameter wires, so that as you modify the original master parameter, each slave parameter maintains a constant relationship with the next in a line of parameters.

**Interface**

**Tree Views**

The dialog presents two tree views that display the animatable parameters of all of the visible objects in the scene. The names of the currently selected objects appear at the top. The tree views display the objects in the scene and allow you to select and wire all of the animatable parameters of the objects in the scene and the scene itself.

The tree views are color-coded to show existing wiring. A parameter with a wire controller assigned to it (either as the member of a two-way pair or as the slave in a one-way wire) displays in red. When a wire-controlled parameter is selected, all of the parameters wired directly to it are displayed in green text in the other Tree View. In either case, if the parameter is inside a track that is not expanded, the enclosing track will display in red or green, so you can expand the tracks to find the wires.

**Note:** If you open the Parameter Wiring dialog by wiring two parameters, the tree views initially display only the selected objects, highlighting the parameters that you chose from the pop-up menus during the wiring procedure. If you want to expand the trees, to include all other animatable parameters in the scene, click Show All Tracks.

The buttons above the tree views are:

- **Show All Tracks**—Brings you to the top of the scene object list.

- **Find Next Parameter**—Finds the next wired parameter in the scene, expanding the tree if necessary to show and select it. You can browse through all existing wires by clicking this button repeatedly.

**Note:** If you click a wired parameter, its connections are shown in green on the other tree view. While the wired parameter is highlighted, the Show Next Wire button on the other tree cycles through the green connections only, so you can quickly find the selected wire’s connections.

- **Refresh Tree View Content to Selected Node**—Shows only the node or nodes that are selected in the scene in the tree view. The nodes are shown as currently expanded.

**Control Direction**—The Parameter Wiring dialog provides three direction-control buttons between the tree views. You can choose only one of these at a time. These buttons determine the direction of control, either one-way or two-way:

- **Two-way connection [two-headed arrow]**—Click this to link both parameters to each other, so that changing either parameter affects the other.

- **One-way connection: right parameter controls left parameter [left arrow]**—The right parameter controls the left parameter.
One-way connection: left parameter controls right parameter (right arrow)—The left parameter controls the right parameter.

Note: You can change the direction of a wire at any time by clicking the desired direction button and then clicking Connect or Update.

Connect/Update—The Connect/Update button changes its label depending on whether clicking it would add a new wire to previously unwired parameters (Connect) or change an existing wire's expressions or direction (Update). Changes to existing wires are only applied when you click Update.

Disconnect—The Disconnect button is enabled when you've selected parameters with an existing wire between them. It will remove the wire controller(s) and replace them with the Master parameter’s animation track (if two-way) or with default controllers (if one-way).

Master parameters

The Parameter Wire system provides a way for the pair of wired parameters to be animated as a single system. It does this by setting up a subcontroller on one of the parameters; any animation on this controller drives the Wire Controller pair. The animation subcontroller is always assigned to the master parameter of the wired pair. By default, this is the parameter that is clicked first in the wiring interaction. The master parameter can also be designated with the Master radio buttons beneath the tree views.

The animation subcontroller appears as a nested track inside the master parameter’s track in Track View and its values directly drive and match the master parameter values. If the subcontroller is keyframable (which is the default when a two-way wiring is first established) it can be keyframed by adjustments of either of the wired parameters. This means that if you keyframe the wired pair by adjusting the non-master parameter, the values keyframed into the animation subcontroller are derived from the master parameter transfer expression. Since the wired pair can be animated through either parameter, the choice of master parameter is essentially just a convention.

Transfer Expression boxes

Underneath the parameter trees are the transfer expression text boxes. These expressions determine how changes to each parameter affect the other and are usually inverses of one another.

For more information on expression syntax, see the topic “Script Controllers” in the MAXScript Reference.

When the parameters are first wired, the default expressions are simple 1-to-1 links between the parameters. These expressions can be edited into any valid script fragment that will yield a result of the correct type for its parameter. For example, if you link a parameter such as height (which contains a float value) to a parameter such as position (which contains a point3 value), your expressions must include conversions that produce the same output value type.

For one-way wires, the Expression box for the controlling parameter is unavailable, since there is no Wire controller assigned to it.

For two-way wiring, both transfer expression text boxes will be enabled. It is possible for the user to supply transfer expressions for the two parameters that are not inverses of one another, but this is of course discouraged, since the relationship of the parameters will be different depending on which one is changed first.
Hierarchies and Kinematics

When animating characters, mechanical assemblies, or complex motion, you can simplify the process by linking objects together to form a hierarchy (page 3–951) or chain. In a linked chain, the animation of one member can affect some or all of the others, making it possible to animate a number of objects or bones at once.

The term kinematics (page 3–960) describes the movement or animation of the chain. There are two types of kinematics:

- With forward kinematics (page 3–944) (FK), you transform a parent object to move its descendants (its children, their children, etc.).
- With inverse kinematics (page 3–958) (IK), you transform a child object to move its ancestors (its parent and so on up the chain). You can also use IK to make an object “stick” to the ground or another surface, while allowing the chain to rotate off the pivot of that object.

Forward kinematics is the most straightforward method for animating hierarchies. Inverse kinematics requires more setup than forward kinematics, but is more intuitive for complex tasks such as character animation.

Hierarchies (page 2–416)
Animating with Forward Kinematics (page 2–426)
Inverse Kinematics (IK) (page 2–435)
Hierarchy Panel Commands (page 2–487)

Hierarchies

One of the most useful tools in producing computer animation is the ability to link objects together to form a chain. By linking one object to another, you create a parent-child relationship. Transforms applied to the parent are also transmitted to child objects. A chain is also referred to as a hierarchy.

You can find the commands to build and manipulate hierarchies in the following places in the interface:

- The Bones system (page 1–404) in the Create panel > Systems category lets you create a hierarchy of bones. You can also create bones by choosing Bone Tools (page 1–411) from the Animation menu (page 3–681). You can turn any hierarchy of objects into bones by selecting the hierarchy and turning on Bone Tools dialog > Object Properties rollout > Bone On.
- The Hierarchy panel (page 3–773) contains commands to control how links behave.
- The Motion panel (page 2–463) contains commands to control how links behave when using an History Dependent (HD) Solver.
Common Uses for Hierarchies

- Link a large collection of objects to a single parent so they can be easily animated and transformed by moving, rotating, or scaling the parent.
- Link the target of a camera or light to another object so it tracks the object through the scene.
- Link objects to dummy objects to create complex motions by combining multiple simple motions.
- Link objects to simulate jointed structures to animate characters or mechanical assemblies.

Parts of a Hierarchy

The relationship between objects linked together in a hierarchy is analogous to a family tree.

**Parent**—Object that controls one or more children. A parent object is often controlled by another superior parent object. In the following figure, objects 1 and 2 are parent objects.

**Child**—Object controlled by its parent. A child object can also be a parent to other children. In the following figure, objects 2 and 3 (the support and hub) are children of object 1. Objects 5 (the seats) are children of object 4, the Ferris wheel.

**Ancestors**—Parent and all of the parent’s parents of a child object. In the following figure, objects 1 and 2 are ancestors of object 3.

**Descendants**—Children and all of the children’s children of a parent object. In the figures, all the objects are descendants of object 1.

**Hierarchy**—Collection of all parents and children linked together in a single structure.

**Root**—Single parent object that is superior to all other objects in the hierarchy. All other objects are descendants of the root object. In the figures, Object 1 is the root.

**Subtree**—All the descendants of a selected parent. In the figure below, the Rotational Hub, Ferris Wheel, and Seats represent the subtree under the Support object.
Chapter 12: Animation

1. Root
2. Leaves
3. Subtree

Example of a hierarchical structure

Branch—Path through the hierarchy from a parent to a single descendant. In the figure above, the Support, Rotational Hub, and Ferris Wheel objects comprise a branch from the root to the leaf objects (the seats).

Leaf—Child object that has no children. The lowest object in a branch. In the figure above, the Seat objects are leaf objects.

Link—Connection between a parent and its child. A link transmits position, rotation, and scale information from parent to child.

Pivot—Defines the local center and coordinate system for each object. You can think of a link as the connection between the pivot of a child object and the pivot of its parent.

Linking Strategy

Before you begin linking any but the simplest hierarchy you should take a few minutes to plan your linking strategy. Your choices for the root of the hierarchy and how the branches grow out to the leaf objects will have important effects on the usability of your model.

The strategy behind linking objects into a hierarchy can be reduced to two main principles:

- The hierarchy follows a logical progression from parent to child.
- Parent objects move less than their descendants.

Within these two principles you have almost unlimited flexibility as to how you link your objects. If you think about how you intend to use the hierarchy, and link it with that use in mind, you will rarely have a problem.

Progression from Parent to Child

Progression from parent to child means the links do not erratically jump from object to object. If two objects touch each other they should probably be linked as parent and child. There is nothing to prevent you from linking a body in the order of: Thigh->Foot->Shin->Waist. You would probably regret such a linking strategy later. The effort to figure out how to transform objects linked in such a strange way would be quite difficult. A more logical progression would be Foot->Shin->Thigh->Waist.

Using Multiple Hierarchies

Rather than build a single bone chain from a hip to a toe, you can make one chain from the hip to the ankle, and then a second independent chain from the heel to the toe. You would then link the chains together to form a complete leg assembly.

Because they are linked together, the leg and foot chains could be considered one chain. However, the way you animate them treats each chain separately, allowing fine control over the parts.

With this type of arrangement on leg and foot chains, the foot could be made to stay on the ground while the leg bends. It also allows for independent control of the foot’s rotation, pivoting on the heel or toe, which would then cause the knee to bend.
Parents Move Less Than Descendants

Because of the way transforms are inherited from parent to child, small adjustments to a parent object might require you to adjust all of its descendants. The typical approach to linking is to choose as your root object the object that moves the least. Objects close to the root should move very little, and leaf objects should move the most.

This is especially true when you are linking jointed structures like robots or machinery, or intend to use the hierarchy with inverse kinematics (page 2–435).

An exception to this rule occurs when you are using the root object as a handle. All of the descendants of the root are just along for the ride. Consider a tray full of objects traveling on a conveyor belt. All the objects should be children of the tray even though the tray moves much more than any of the other objects.

Choosing the Root of a Hierarchy

You can find the best candidate for the root of your hierarchy by asking the following question:

If I move this object, should all of the other objects in the hierarchy move with it?

- If the answer is almost always, then you are looking at a likely candidate for the root object. Examples of this type of object are a torso, a lamp base, and a tree trunk.
- If the answer is not often, then you are probably looking at a child object. Examples of this type of object are hands, lamp shades, and tree leaves. If you move a character’s hand, for example, its torso should not move.

Once you have a few candidates for the root object, you can examine them in greater detail. Use these criteria to determine a good root object for your hierarchy:

- Moving the root object usually has a great effect on all other objects in the hierarchy.
- Conversely, the root object is mostly unaffected by movement of other objects in the hierarchy.
- The root object is rarely animated, and is moved or rotated primarily to place the hierarchy at the correct place in the scene.
- The root object is at or near the hierarchy’s virtual center of mass.

The object that best satisfies these criteria is your root object. You then create your hierarchy with all of the other objects as descendants of that root object.

Linking Objects for Inverse Kinematics

Inverse kinematics (IK) uses the child object as the driving force for the animation. IK is less forgiving and is highly dependent on the linking strategy for performing calculations.

You need to consider two additional principles when linking hierarchies for use with inverse kinematics:

- Links and pivot placement simulate real-world joint locations.
- Choose an object near the structure’s center of mass, or center of gravity, as the root of the hierarchy. The center of mass in the real world is the point on an object about which reactions to external forces are applied.
Chapter 12: Animation

1 and 2 each represent the root of the characters. Both structures are suitable for forward kinematics. The structure on the right is best for most inverse kinematics.

The figure above shows two approaches to linking a skeletal structure. Either structure is suitable for working with forward kinematics. The structure on the right, however, is a better choice for working with inverse kinematics.

- The root object is located near the body’s center of mass.
- The link order more closely simulates the connections of a real body.

The structure on the left has the arms and torso linked to the neck. The structure on the right links the arms and neck to the torso, a more realistic approach.

**Warning:** Be sure to avoid using non-uniform scaling on objects in a hierarchy that will be animated using IK. You will see stretching and skewing if you do. Instead do all non-uniform scaling at the sub-object level, to avoid this problem. Use Reset XForm if you have objects that exhibit this behavior.

---

**Linking Objects After Animation**

When you link an object to another, the link relationship between the child and its parent is determined by the position, rotation and scale of the parent and child objects when the link is made.

Imagine linking a stationary sphere to an animated box.

- At frame 0 the box is beside the sphere.
- At frame 50 the box is 20 units away.

---

*Original animation, with ball unlinked and stationary while the box moves.*

Linking the sphere to the box causes the sphere to move with the box. The distance between the sphere and the box depends on the frame when the link is made. Linking the sphere on different frames has the following effects:

- Link on frame 0, and the sphere stays next to the box as it moves.
- Link on frame 50, and the sphere stays a distance 20 units away from the box as it moves.
Linking and Unlinking Objects

When you unlink a child, its frame 0 transforms are taken from the transforms of its parent at the frame when the link is removed.

Imagine a sphere linked to a box moving around the face of a clock. The box starts at 12 o’clock and travels all the way around the face over 100 frames. The figure shows a box moving in a circle with a sphere linked above it.

Unlinking Objects After Animation

If you unlink the sphere, it stops following the box. The position of the sphere depends on its position, rotation or scale at the frame on which the link is removed. Unlinking the sphere on different frames has the following effects:

- Unlink on frame 0, and the sphere stays at 12 o’clock.
- Unlink on frame 25, and the sphere stops at 3 o’clock.
- Unlink on frame 75, and the sphere stops at 9 o’clock.

Linking Objects

The general process of creating links is to build the hierarchy from child to parent. You click Select And Link on the toolbar, select one or more objects as children, and then drag the link cursor from the selection to a single parent object. The selected objects become children of the parent object.

Once objects are linked, any transformations applied to the parent are also applied to its children. For example, if you scale the parent to...
150%, the size of its children and the distance between the children and the parent are also scaled by 150%.

**Unlinking Objects**

Click Unlink Selection to remove the link from selected objects to their parents. Any children of the selected object are unaffected.

You can quickly unlink an entire hierarchy by double-clicking the root object to select the object and all of its children. Then click Unlink Selection.

**Linking Animated Objects**

You should establish links before you begin animating objects. The linkage of objects with Select and Link cannot be animated; the link remains in force throughout the entire animation.

If you want your objects to be linked during one part of the animation but not another, you can a Link constraint (page 2–403) to change the linkage at specific frames.

**Displaying Links**

A complex mesh hierarchy can be displayed with the links visible, or even with the links replacing the mesh objects. To display links, first select the linked objects. On the Display panel > Link Display rollout (page 1–58), turn on Display Links to see the links. You can also turn on Link Replaces Object to see only the links and not the objects.

---

**Select and Link**

Use the Select and Link button to define the hierarchical relationship (page 3–951) between two objects by linking them as child and parent.

You link from the currently selected object (child) to any other object (parent).

You can link an object to a closed group. When you do, the object becomes a child of the group parent rather than any member of the group. The entire group flashes to show that you’ve linked to the group.

A child inherits the transformations (move, rotate, scale) applied to the parent, but the child’s transformations have no effect on the parent. If you want the child not to inherit the transforms, use the Link Inheritance (Selected) Utility (page 2–435) or use the controls found in Link Info (page 2–499) in the Hierarchy panel.

You can also create hierarchical linkages using Schematic View (page 3–638). Use the Connect button on the Schematic View toolbar to create hierarchical linkages between nodes.

**Procedure**

**To link two objects:**

1. Click Select and Link.
2. Drag a line from an object (the child) to any other object (the parent).

**Note:** You do not need to select the child object first.

---

**Unlink Selection**

Use the Unlink Selection button to remove the hierarchical relationship (page 3–951) between two objects.

Unlink Selection detaches a child object from its parent object.
Tip: You can also link and unlink hierarchies in Schematic View (page 3–640).

Procedure
To unlink a child object from a parent object:
1. Select the child object you want to unlink.
2. Click Unlink Selection.

Adjusting Pivots
You can think of an object’s pivot point as representing its local center and local coordinate system. The pivot point of an object is used for a number of purposes:
- As the center for rotation and scaling when the Pivot Point transform center is selected.
- As the default location of a modifier center.
- As the transform offset for linked children.
- As the joint location for IK.

You can adjust pivot points by clicking Pivot on the Hierarchy panel, and then using features on the Adjust Pivot rollout (page 2–488).

The functions under the Adjust Pivot rollout cannot be animated. Adjusting an object’s pivot on any frame changes it for the entire animation.

Affecting Pivot Only
When Affect Pivot Only is on, move and rotate transforms are only applied to the pivot of a selected object.
- Moving or rotating the pivot does not affect the object or its children.
- Scaling the pivot scales the object from the pivot center, but its children are unaffected.

Affect Pivot Only transforms the pivot without moving the object.

Affecting Object Only
When Affect Object Only is on, transforms are applied only to selected objects. Pivots are not affected.

Moving, rotating, or scaling the object does not affect the pivot or its children.

Affect Object Only transforms the object without moving the pivot.

Affecting Hierarchy Only
When Affect Hierarchy Only is on, Rotate and Scale transforms are applied only to the links between objects and their children.
- Scaling or rotating an object affects the link offsets of all its descendents without affecting
the geometry of the object or its descendents. The descendents shift position because of the scaled or rotated links.

Use this technique to adjust the offset relationship between linked objects.

Use this technique to adjust the offset relationship between linked objects and for adjusting bones to match geometry.

After a hierarchy is created, you can scale the position of the children without changing the individual objects' dimensions.

Alignment is disabled when Affect Hierarchy Only is active.

Center to Object/Pivot—Moves the object, or pivot, so the pivot is at the center of the object.

Align to Object/Pivot—Rotates the object, or pivot, to align the pivot with the object’s original local coordinate system.

Align to World—Rotates the object, or pivot, to align with the world coordinate system.

Resetting the Pivot

Click Reset Pivot to return the pivot point of a selected object to the position and orientation it held when the object was first created.

Reset Pivot has no effect on the object or its children. The state of the Affect Pivot Only and Affect Object Only is ignored.

Viewing and Selecting Hierarchies

There are a number of ways to view a hierarchy structure and select objects in it.

Viewing a Hierarchy

You can use these methods to view the relationships between parents and children in a linked hierarchy.

- The Select Objects dialog (page 1–78) appears whenever you use a by-name selection method, such as choosing Edit menu > Select By > Name, by clicking Select By Name on the main toolbar, or by pressing the \[H\] key.

To list objects hierarchically, turn on Display Subtree on the dialog. This indents children below their parent.

- The Hierarchy list (page 2–512) at the left side of the Track View window (page 2–501) displays all objects using indentation to express hierarchy. Child objects are displayed indented and below their parent. An added advantage of Track View
is that you can control the view by collapsing and expanding branches of the hierarchy.

Selecting Hierarchy Members: Ancestors and Descendants

Once you have selected one or more objects in a hierarchy, you can select its direct ancestor or descendant with the \[\text{Page Up}\] and \[\text{Page Down}\] keys.

- \[\text{Page Up}\] deselects the object and selects the object’s parent.
- \[\text{Page Down}\] deselects the object and selects all its immediate children, but not all descendants down the chain.

Tip: These navigation commands are particularly useful when setting joint parameters for inverse kinematics.

To select an object and all of its descendants, you can:
- Double-click the object in a viewport.
- Double-click the object icon in the Track View Hierarchy list (page 2–512).

Selecting Hierarchy Members: Siblings

Available in Customize User Interface (page 3–792) are the actions Select Sibling - Next and Select Sibling - Previous, which you can assign as hotkeys, toolbar buttons, etc. We recommend assigning them to the cursor keys [Right Arrow] and [Left Arrow] respectively; by default, those keys are not assigned keyboard shortcuts.

Using one of these commands replaces the current selection with one object only at the same hierarchical level. More precisely, a sibling is defined in this context as an object of equal generational distance from the selected object’s nearest parent. All objects that fit this definition are siblings, so that in asymmetrical hierarchies, object A can be a sibling of object B, but the reverse is not necessarily the case.
Take, for example, the asymmetrical hierarchy of dummy helper objects shown below:

At first glance it might appear that Dummies 06, 08 and 02 are siblings of each other, but in practice it is more complicated:

- Selecting Dummy06 and activating Select Sibling - Next results in Dummy08 being selected.
- Selecting Dummy06 and activating Select Sibling - Previous results in Dummy02 being selected.
- With Dummy02 selected, activating either Select Sibling command results in Dummy08 being selected, and the selection continues alternating for each subsequent invocation of either command. This is because 3ds Max looks only as far as the next branch above the selected object, resulting in Dummies 02 and 08 being siblings of Dummy06, but not vice-versa.

Defining a sibling in this way has the practical advantage of letting you, for example, cycle through the selection of all finger links on one side of a character without the selection jumping to the other hand. But cycling through siblings with an arm object selected usually results in selecting the opposite arm object.

When using these commands, hidden (page 3–951) and frozen (page 3–945) objects can't be selected, but are considered part of the hierarchy when deciding what is and is not a sibling. Also, if a selection filter (page 1–68) is active, siblings that don't meet the filter's criteria cannot be selected. In all such cases, ineligible siblings are skipped in favour of a further sibling, if any exists.

**Customizing the Quad Menu**

You can customize the quad menu (page 3–694) so it displays commands to select children, or ancestors, or both. From the Customize menu, choose Customize User Interface (page 3–792). On the Quads (page 3–795) tab, drag Select Ancestor or Select Children from the list of all commands to the quad menu. Then you can easily select children or parents with a right-click and then a click.

---

**Animating with Forward Kinematics**

The default method of manipulating a hierarchy uses a technique called forward kinematics (page 3–944). The basic principles employed by this technique are:

- Hierarchical linking from parent to child
- Placement of pivot points to define the connecting joint between linked objects
- Inheritance of position, rotation, and scale transforms from parent to child

You animate the objects of a hierarchy in much the same way you animate anything else. Turn on the Auto Key button and transform members of the hierarchy at different frames. However, you need
to be aware of a few special issues for animating hierarchies.

**How Links and Pivots Work**

Once two objects are linked together, the child object maintains its position, rotation, and scale transforms relative to its parent object. These transforms are measured from the pivot of the parent to the pivot of the child.

For example, consider the two boxes in the following figure. The larger box is the parent of the smaller. The pivots and link between the boxes are indicated to show how the link works. The link extends from the pivot of the parent and connects to the pivot of the child. You can think of the child’s pivot as being the joint between the parent and child.

Links act as a one-way conduit to transmit the transforms of a parent object to its child object. If you move, rotate, or scale the parent, the child is moved, rotated, or scaled by the same amount. Because hierarchical links are one-way, moving, rotating, or scaling the child has no effect on its parent.

The end result is that transforms applied to a child object are applied in addition to any transforms inherited from the child’s parent.

**Animating a Parent Object**

Only transforms are passed from parent to child. Animating a parent object using move, rotate, or
scale animates the parent and the subtree attached to the parent.

Animating a parent’s modifiers or creation parameters has no effect on its descendants.

Moving the root parent moves the whole hierarchy.

Rotation of a parent object is passed to all the child objects.

Moving the last child object does not affect any of the previous objects in the hierarchy.

Rotating a child object in the middle of the hierarchy affects all the descendants but none of the parents.

If you want to manipulate parent objects by moving the last child in the chain, use inverse kinematics (page 2–435).

### Animating a Child Object

With forward kinematics, a child is not constrained by its link to a parent. You can move, rotate, and scale children independent of their parents.

### Manipulating the Hierarchy

A child object inherits the transforms of its parent, and the parent inherits the transforms of its ancestors all the way up the hierarchy to the root object. Because forward kinematics employs this method of inheritance, you must position and animate your hierarchies using a top-down method.
Manipulating the hierarchy of a leg.

Consider the linked mannequin in the figure. If you want to position the mannequin’s right foot to rest on top of the soccer ball beside it, you perform the following steps:

1. Rotate the right thigh so the entire leg is above the soccer ball.
2. Rotate the right shin so the foot is near the top of the soccer ball.
3. Rotate the right foot so it is parallel with the top.
4. Repeat steps 1 through 3 until the foot is properly placed.

You always start transforming objects at the highest-level parent affected by the motion and work your way down the hierarchy to the last child.

You have considerable control over the exact placement of every object in the hierarchy using forward kinematics. However, the process can become tedious with large and complex hierarchies. In such situations, you might want to use inverse kinematics (page 2–435).

Using Dummy Objects

The primary use of dummy helper objects (page 2–16) is to assist in creating complex motions and building complex hierarchies. Because dummies are invisible when rendered, they are an excellent choice for offset joints, connectors between objects, and handles for complex hierarchies. Dummies and Points (page 2–23) can act as null objects that function as controls for transforming parts of an IK chain.

Using a Dummy to Control Motion

Breaking complex motions into simple components often makes it easier to go back and edit your animations.

Consider a bouncing ball that moves along a path. You could animate the ball by positioning it on many frames, but it would be very difficult for you to go back and adjust the height of the bounce or the path of the ball. You have to edit the motion of the ball on many frames to make even a simple change.

Using a dummy object solves this problem by breaking the motion into simple components. One component is the up and down bounce of the ball. The other is movement on the path.

Combining the bouncing motion of a ball with the forward motion of a dummy results in a moving bouncing ball.
Using a Dummy as a Handle

You might want to move and animate a selection of objects individually but also have the ability to transform them as a single object.

A good example of this is a camera on a tripod. You want to adjust both the camera and its target individually but also want to move them together as a single unit.

Procedures

To create a complex bounce motion using a dummy object:

1. Start with a sphere, then create a dummy object below the sphere, and link the sphere as a child of the dummy.
2. Animate the sphere bouncing up and down above the dummy.
3. Animate the dummy moving.

   The sphere bounces on top of the dummy object as the dummy moves around the scene. You can easily change the height and speed of the bounce by changing the sphere animation. You can change the path through the scene by changing the dummy animation.

To create a camera tripod:

   • Create a dummy object below a target camera and link the camera and target as children of the dummy object.

   The camera and the target follow the dummy object. You can quickly position the camera by placing the dummy object and compose your view by adjusting the camera and its target.

Animating Links

You assign a Link constraint (page 2–403) to an object to animate links from one parent to another. You use a link constraint instead of using the regular Select and Link and Unlink Selection buttons on the toolbar. (See Animation Constraints (page 2–392).)

An example of using a link constraint is to pass a ball from one hand to another. Assume that at frame 0 the ball is in the first hand. The hands are animated to meet at frame 50 and then spread apart until frame 100.

To animate the links for the ball:

1. On the Motion panel, assign a Link constraint as the ball’s Transform controller. You can also put a Link constraint on the ball from the Animation menu by choosing Constraints > Link Constraint.
2. Move the time slider to frame 0, then on the Motion panel click Add Link, and click the hand holding the ball. The ball will now move along with the hand, as if it were linked to it.
3. Move the time slider to frame 50, where you want the second hand to pick up the ball, click Add Link, then click the second hand. From this frame on, it’s as if the ball were linked to the second hand.

When you play back the animation, the ball travels with the first hand until frame 50, where you added the second link, then the ball is passed to the second hand for the rest of the animation.
Adding and Deleting Links

You add and delete links on the Motion panel. Expand the Link Parameters rollout and click Add Link or Delete Link.

- Click Add Link then click the object that you want to link to as a parent. The frame at which you add the link is the frame at which control is passed. You can change the link frame with the Start Time parameter.
- Click the name of a parent object in the list, and then click Delete Link to remove the link.

Properties of the Link constraint include:

- The Link constraint respects the link inheritance settings applied to the child object.
- The object using a Link constraint is not a true child object. It does not appear in the subtree of any linked parent objects.
- Objects with Link constraint do not participate in IK solutions.

Link to World

You can also link an object to the world using the Link to World button. This will keep the object stationary without the use of a dummy object. Just click Link to World and the world is automatically entered as a Target.

Key Modes

You can choose between three different key modes, which determine how keyframes are written on the linked objects as part of the link constraint. These options provide the following:

- No Key Mode—No keys are created any of the objects involved. No keys will be visible in the track bar.
- Key Nodes—Sets keys for some of the objects. Child applies keys to the child object only. Parents applies keys to both parents and the child object.
- Key Entire Hierarchy—This applies keyframes to the chosen nodes and their entire hierarchies. Child keys the chosen object and the nodes in its hierarchy up to the world. Parents keys both parents and the child and all three hierarchies up to the world.

Side Effects of the Link Constraint

The Link constraint works to keep a child object from jumping position at the time when the link changes from one parent to another parent.

Considering the previous example, the following should hold true:

- During frames 0 to 50 the ball remains constant relative to the first hand.
- During frames 50 to 100 the ball remains constant relative to the second hand.
- At frame 50, the time when link control changes, the ball does not jump.
If you change the animation of the second hand at frame 75, it affects the position of the hand relative to the ball at the time of the link (frame 50). This change in relative position affects the ball over all frames where it is linked to the second hand. Therefore, as you change the position of the hand at frame 75, the child's position will also change, possibly in a counter-intuitive way. However, when playing back the animation the above three rules will hold true.

Adjusting Object Transforms

You use the features on the Adjust Transform (page 2–489) rollout to transform objects after they have been linked without transforming descendents, and to reset an object's transform.

Transforming Parent Objects

You might discover, after linking a number of objects, that you need to move, rotate, or scale a parent object but you do not want to affect the object's descendents. You can transform a parent object without affecting its descendents by clicking Don't Affect Children on the Adjust Transform rollout of the Hierarchy panel.

Resetting an Object’s Orientation and Scale

Click the Transform button in the Reset group to rotate an object's pivot to match its parent's local coordinate system. Descendents of the object are not affected.

Resetting an Object’s Scale Only

Click the Scale button in the Reset group to set the current scale value as the selected object's base scale value. All following scale transforms are then applied using the base scale value as an absolute local scale of 100%.

Consider a sphere with a radius of 20 units and a linked child object:

1. Use Uniform Scale to scale the sphere to 200%. The sphere and its child become twice as big. Scale Transform Type-In reports an Absolute Local Scale of 200% and the object’s creation parameters report a radius of 20 units. The true radius of the sphere is 200% of 20 units, or 40 units.

2. Select the sphere and click Reset Scale. The sphere and its child remain the same size. Here's what has happened:

   The 200% scale has been absorbed by the sphere as its original state. The sphere has a true radius of 40 units, Creation Parameters report a radius of 20 units, and absolute local scale is 100%.

   The sphere's child object accepts a local scale of 200% so it does not change in size.

Resetting the scale of an object can lead to confusion because the object's true size, absolute local scale, and creation parameters no longer match up.

Using the Reset Transform Utility

You can also reset the orientation and scale of an object by clicking Reset XForm (page 1–438) on the Utilities panel (page 3–778). Reset XForm takes the rotation and scale transforms of an object and places them in an XForm modifier on the modifier stack.

Consider the same sphere as before with a radius of 20 units and a linked child object:

1. Use Uniform Scale to scale the sphere to 200%. The sphere and its child become twice as big. The Scale Transform Type-In reports an Absolute Local scale of 200% and Creation Parameters report a radius of 20 units. The true radius of the sphere is 200% of 20 units, or 40 units.
2. Select the sphere and click Reset XForm. The sphere remains the same size but its child reverts to its original size and position. Here’s what has happened:

The 200% scale has been placed in an XForm modifier on the sphere’s modifier stack. The sphere has a true radius of 40 units, Creation Parameters report a radius of 20 units, and absolute local scale is 100%.

The sphere’s child object now sees only the 100% local scale so it reverts to its original size and position.

Locking Object Transforms

You can lock an object’s ability to move, rotate, or scale about any of its local axes by selecting objects and then setting options on the Locks (page 2–500) rollout of the Hierarchy panel.

Enabling and disabling Local transform axes is also referred to as setting degrees of freedom (DoF) for an object. If an axis is enabled, an object is free to transform about that Local axis.

The Locks rollout contains three groups: one each for Move, Rotate, and Scale. Each group contains three options, one each for the X, Y, and Z Local axes of the selected objects.

- When turned on, the objects cannot be transformed about the selected Local axes when you directly use one of the transform tools.
- Objects can still be transformed by other means such as being a child of a transformed parent object or being part of an inverse kinematics chain.
- When turned off, objects can be freely transformed about the unlocked Local axes.

Animating Attachment

You assign an Attachment constraint (page 2–393) to cause an object to hold a position on the surface of another object. The Attachment constraint is not a hierarchical link, but it has the effect of “linking” an object to the surface of another object as follows:

- Attach a "source" object to the face of a "target" object so that the source object acts as if it’s glued to the target object, no matter how the surface of the target object is deformed.
- Animate the Attachment parameters so that the source object moves over the surface of the target object.

Unlike hierarchical linking, which considers only object transforms, an object using an Attachment constraint follows the deformations of another object based on that object’s modifiers and space warp bindings.

See Animation Constraints. (page 2–392)

Setting Attachment Parameters

You use features on the Attachment Parameters rollout on the Motion panel, to pick a target object and position the source object.

- Click Pick Object, then click the target object to perform the attachment.
- Click Set Position and click or drag on the surface of the target object to place the source object onto the surface.

If you want to move the source object along the normal of the face (move it below or above the face) click Affect Object Only on the Hierarchy panel and move the object, using Local transform coordinates.

- Turn on Align to Surface if you want to align the world Z axis of the source object with the surface normal of the target object. Even with
Align to Surface selected, you can always rotate the source object to orient it the way you want in relation to the target object.
If you were to align trees on an uneven terrain, you would turn off Align to Surface so that all of the trees grew upright, regardless of the angle of the terrain surface.

**Aligning Attachment Position**
You can move to any frame and click Set Position to animate the source object moving across the surface of the target object. It is not necessary to turn on the Auto Key button, because you are working with an animation constraint.
When you set positions for the source target on multiple frames, its attachment to the target object is only fixed at each keyframe. Frames between keys are interpolated and might not match the target surface. If you need the object to remain on the target surface, try using a Surface Constraint, rather than attachment.
Test your animation, and either adjust the values of the keys, or add intermediate keys to better match the target surface. Too many keys can result in jittery movement of the source object, while too few keys might result in the source object missing the surface of the target object over some frames.

**Changing Link Inheritance**
Links can transmit transform information from a parent to a child. By default, a child inherits all of the transforms of its parent. To set an object’s ability to inherit the move, rotate, and scale transforms of its parent, you use the Inherit (page 2–500) rollout of the Hierarchy panel. Use its settings to limit which transforms a child inherits.
The Inherit rollout is available only when you have selected a single object. When multiple objects are selected, the rollout is disabled.

**Setting Link Inheritance Options**
Set the Inherit options to release the link components between a selected object and its parent for any world axis of Move, Rotate, or Scale.
The options that appear when you expand the Inherit rollout are determined by the transform controllers assigned to the selected object.
The Inherit rollout for objects using standard position, rotation, and scale controllers contains three groups: one each for Move, Rotate, and Scale. Each group contains three options, one each for the X, Y, and Z world axes.
- When turned on, transform information from the parent is passed on to the child for the selected World axes.
- When turned off, transform information for the selected axes is ignored by the child.
Imagine you are animating a Ferris wheel that rotates on the world Y axis. The wheel is the parent and the cars are its children. You want the cars to ignore the Y axis rotation of the wheel. Otherwise, the passengers would all fall out. You use Link Info to turn off the Y axis option on the Rotation group of the Inherit rollout for each car.

**Using the Link Inheritance Utility**
The Link Inheritance (page 2–435) utility works exactly the same as the Inherit rollout in the Link Info group on the Hierarchy panel, except that you can set link inheritance for multiple objects in a selection set.
For example, on a Ferris wheel, you could select all of the cars and use the Link Inheritance utility to turn off Y axis rotation for all the cars at once.
Link Inheritance (Selected) Utility

Utilities panel > Utilities rollout > More button > Utilities dialog > Link Inheritance (Selected)

The Link Inheritance (Selected) utility constrains the links between multiple objects in a selection set for any axis of position, rotation, or scale.

This utility works exactly the same as the Inherit rollout (page 2–500) in the Link Info group box in the Hierarchy panel (page 3–773), except that it lets you adjust link inheritance for multiple objects in a selection set, while the functions in the Hierarchy panel work only on single objects.

Procedure

To prevent the inheritance of X rotation in a hierarchy:

- Select one or more objects, and then turn off X in the Rotate group of the Inherit rollout.

Interface

```
- Link Inheritance [Selected]

  Move:
  ☑ X ☑ Y ☑ Z

  Rotate:
  ☑ X ☑ Y ☑ Z

  Scale:
  ☑ X ☑ Y ☑ Z
```

XYZ—Turn off any axis in the Move, Rotate, or Scale groups to prevent inheritance.

When a box is turned on, transform information from the parent is passed on to the selected objects for the selected axis. When a box is turned off, transform information on that axis is ignored by the selected objects.

Animating with Inverse Kinematics (IK)

Using IK to animate a leg

Inverse kinematics (IK (page 3–958)) is a method of animating that reverses the direction of the chain manipulation. Rather than work from the root of the tree, it works from the leaves.

Let’s take the example of an arm. To animate an arm using forward kinematics, you rotate the upper arm away from the shoulder, then rotate the forearm, the hand from the wrist and so, on adding rotation keys for each child object.

To animate the arm using inverse kinematics, you move a goal that positions the wrist. The upper and lower arms are rotated by the IK solution which moves the pivot point of the wrist, called an end effector (page 3–933), toward the goal.

In the case of a leg, for example, the foot is constrained to the floor by the goal. If you move the pelvis, the foot stays put since the goal has not moved, and this causes the knees to bend. The entire animation is contained in keyframes for the
Chapter 12: Animation

goal and the root, without keys being applied to the individual chain objects.

With inverse kinematics you can quickly set up and animate complex motions. The basic procedure involves these tasks:

- Building a model. It could be a jointed structure or many pieces or a single continuous surface.
- Linking the jointed model together and defining pivot points, as described in Hierarchies (page 2–416).

For a continuous-surface model, create a Bone (page 1–404) structure to animate the skin of the character.

- Applying IK solvers (page 2–440) to either the jointed hierarchy or to the bones. You will probably create several IK chains throughout the hierarchy, rather than just one. You might also create several independent hierarchies, rather than linking everything together in one large hierarchy.
- Defining joint behavior (page 2–483) at the pivot points, setting limits or preferred angles, depending on the type of IK solvers you are using. Here you can set up sliding joints or rotating joints. You might also need to move the root of the hierarchy, as well. You might also want to add control objects such as dummies at this point.
- Animating the goal (in the case of an HI Solver (page 2–446) or IK Limb solver (page 2–472)) or the end effector (in the case of the HD Solver (page 2–461)). This animates all the components of the IK chain.

You can apply constraints (page 2–392) to the goals or control objects or to the root of a chain.

You can externally reference IK chains in your scene. An XRef IK chain behaves the same as a non-XRef chain, except that you cannot retarget its XRef controller (page 2–383) once it is in your master scene. For more information, see XRef Objects (page 3–394).

Control Objects to Assist IK

You can link a goal or an end effector to points, splines, or dummy objects that serve as quick controls to translate or rotate the end of the chain. These control objects can be linked together as well, or they can be controlled with constraints. You can also use parameter wiring to build relationships between these control objects.

You can wire control objects to manipulator helpers (page 2–27) or to custom attributes (page 1–129), creating an easily accessible interface for your animatable model.

You can add further controls to manipulate the elements in the middle of the chain.

Note: In the HI Solver (page 2–446), the swivel angle (page 2–449) has its own manipulator, which can be animated or linked to another target object.

Differences Between Forward and Inverse Kinematics

Forward kinematics uses a top-down method, where you begin by positioning and rotating parent objects and work down the hierarchy positioning and rotating each child object.

Basic principles of forward kinematics include:

- Hierarchical linking from parent to child.
- Pivot points defining joints between objects.
- Children inheriting the transforms of their parents.

These principles are fairly forgiving. As long as everything is linked together and the pivots are located at joint locations, you can successfully animate the structure.

Inverse kinematics (IK) uses a goal-directed method, where you position a goal object and the
program calculates the position and orientation of the end of the chain. The final position of the hierarchy, after all of the calculations have been solved, is called the IK solution. There are a variety of IK solvers that can be applied to a hierarchy.

Inverse kinematics starts with linking and pivot placement as its foundation and then adds the following principles:

- Joints can be limited with specific positional and rotational properties.
- Position and orientation of parent objects are determined by the position and orientation of child objects.

Because of these additions, IK requires greater thought about how you link your objects and place pivots. Where many different solutions for linking objects may be suitable for forward kinematics, there are usually just a few good solutions for any given IK approach.

Inverse kinematics is often easier to use than forward kinematics, and you can quickly create complex motions. If you need to edit those motions later, it can be simpler to revise the animation if you are using IK. It also is the best way to simulate weight in an animation.

IK Terminology

Using inverse kinematics requires that you set parameters for a number of IK components. Brief definitions of these components follow; details are provided in other topics.

Note: 3ds Max offers a variety of inverse kinematics systems. There are four kinds of IK solvers, plus applied IK and interactive IK systems that don’t use IK solvers. Not all of the following parameters are used by all the systems.

**IK Solvers**—An IK solver applies an IK solution to a kinematic chain. The kinematic chain is composed of a bones system, or a set of linked objects.

**Joints**—An IK joint controls how an object transforms with respect to its parent. You specify joint behavior with settings in three categories:

- **Object Pivot Point**—The location of an object’s pivot point defines where joint motion is applied.
- **Joint Parameters**—Changing the IK settings in the Hierarchy command panel determines the direction, constraints, and order of how the joint operates.
- **Parent Pivot Point**—The location of an object’s parent pivot point defines the origin from which the joint constraints are measured.

The commands you use to place the pivot points for both the object and its parent are described in Adjusting Pivots (page 2–423).

**Start and End Joints**—The start and end joints define the beginning and end of an IK chain managed by the IK solver. The hierarchy of the chain determines the direction of the chain. The pivot point of the end joint is displayed as the end effector, when end effector display is enabled.

**Kinematic Chain**—Inverse kinematics calculates the position and orientation of objects in a kinematic chain. The kinematic chain is defined as any part of a hierarchy under IK control. The IK chain starts with a selected node and consists of a start joint and an end joint. The base of the chain is either the root of the entire hierarchy, or an object
that you specify as a terminator for the chain. The
kinematic chain is defined when you apply an IK
solver to a chain, or when you create a bone chain
with an IK solver automatically applied.

**Goal**—The goal is used by the HI Solver to
manipulate the end of the chain. When the goal is
animated, the IK solution attempts to match the
end effector (pivot point of the last child in the
chain) to the goal position. When using an HD
Solver, the end effector fulfills the same function
as the goal.

**End Effector**—For any IK solution, you explicitly
move a control object. IK calculations then move
and rotate all other objects in the kinematic chain
to react to the object you move. The object that
you move is the goal, in an HI Solver or IK Limb
Solver, or in the case of an HD Solver, an end
effector (page 3–933).

**Preferred Angle**—Determines which direction a
joint will bend. The preferred angle establishes a
base angle between chain elements when an HI
Solver is applied. The IK Solution seeks this angle
in calculations.

**Solver Plane and Swivel Angle Manipulator**—A
plane can be defined between the start and end
joints, which aids in controlling the IK solution.
Adjust or animate the solver plane by changing
the swivel angle manipulator when in manipulate
mode. This determines an up-vector handle for
the chain, which can also be animated over time.
You can also define a target for the swivel angle
manipulator to follow. For more information, see
*White Paper: Swivel Angle of the HI IK Solver (page
2–449).*

**Terminators**—You can explicitly set the base of an
HD (History-Dependent) IK chain by defining
one or more objects as terminators. A terminator
object stops the IK calculations so that objects
higher up the hierarchy are unaffected by the
IK solution. Terminator objects are also used to
define hierarchies that use multiple HD IK chains.

Terminator objects are not used in HI Solvers or
IK Limb Solvers. In these cases the termination is
determined by the end joint of the chain.

**Bound Objects**—Objects in your hierarchy can be
bound to the world, or they can be bound to other
objects called *follow objects (page 3–943).*

Binding allows objects in your hierarchy to be
influenced by objects that are not part of the
hierarchy.

- An object bound to the world will attempt to
  maintain its current position and orientation.
- An object bound to a follow object will attempt
  to match the position and orientation of the
  follow object.
- You can bind to a follow object when you use
  an HD Solver, or when Applied IK is used.

If you want to bind to a follow object when
using an HI or IK Limb Solver, apply a position
constraint between the goal and any follow
object of your choice (usually a point, dummy,
spline, or bone).

**Enabled IK**—(HI Solver) When using the HI Solver,
you can animate with either inverse kinematics
or forward kinematics (FK). When Enabled is
turned on, inverse kinematics controls the chain,
and keyframes are placed only on the goal. When
Enabled is turned off, forward kinematic rotational
keys are placed on all the bones.

**IK/FK Snap**—(HI Solver) When using the HI Solver,
if you animate using both IK and FK, you might
create a situation where the goal has moved away
from the end of the chain, causing a jump in the
animation. Pressing IK/FK Snap will result in
the goal being moved back to match the position
of the end effector, eliminating the jump in the
animation.
IK for FK pose—(HI Solver) When this button is turned on, moving the goal automatically sets rotation keys for the bones. In effect, this lets you use IK manipulation to create your pose, setting FK keys.

IK Methods
Inverse kinematics builds on the concepts of hierarchical linking. To understand how IK works, you must first understand the principles of hierarchical linking and forward kinematics. See Animating with Forward Kinematics (page 2–426) and Inverse Kinematics (IK) (page 2–435).

IK Solvers
IK solvers (page 2–440) are specialized controllers that apply IK solutions procedurally across a range of frames.

Four different IK solvers ship with 3ds Max:
- HD (History-Dependent) Solver
- HI (History-Independent) Solver
- IK Limb Solver
- Spline IK Solver

Tip: In order to put an IK solver on a two-bone chain, a third bone is needed. Choose the first bone, then from the Create menu click IK solver, then click the third bone in the viewport.

In general, all IK solvers:
- Work on any hierarchy.
- Work on any hierarchy or bone structure.
- Calculate IK solutions for all frames in real-time as you make changes.
- Allow you to create multiple or overlapping IK chains within a single hierarchy.
- Display active joint axes and joint limits graphically.
- Use a node, goal or an end effector to animate the end of a chain.

An IK solver places keyframes only on the IK goal or end effector, as opposed to forward kinematics (or the non-solver IK methods), which place rotation keyframes on the bones or hierarchical objects themselves.

Other IK Methods
In addition to the IK solvers, 3ds Max provides two non-solver methods of inverse kinematic animation: Interactive IK and Applied IK. These IK methods do not apply an IK solver.

Note: These are older IK methods carried over from the earliest versions of the software. It is generally recommended that IK Solvers be used in most cases rather than Interactive or Applied IK.

- Interactive IK (page 2–480)
  Interactive IK gives you the ability to use IK manipulation on hierarchies without applying an IK solver. You animate your IK structure by activating Interactive IK (found in the IK panel of the Hierarchy panel and on the Hierarchy toolbar) and manually animating the position of end effectors. IK solutions are calculated only for the keyframes you set. All other motion is interpolated as set by the object’s controllers. Moving the end of the chain simply adds rotational keys to the objects in the chain. The objects can have joint limits assigned, for additional control. The chain can also be terminated using the tools in the Auto Termination rollout (page 2–499).

- Applied IK (page 2–481)
  With Applied IK, you animate follow objects and the program calculates the solution on every frame of a specified range. The IK solution is applied as standard transform
Chapter 12: Animation

Animation keys. Applied IK works with any linked hierarchy of objects except for bones that use the HI Solver or the IK Limb Solver. It can combine forward kinematics with inverse kinematics on the same objects. You can apply it automatically to a range of frames, or interactively to single frames.

Applied IK is fast and accurate, but it creates keys for every object in the kinematic chain, on every frame. The large number of keys can make it difficult to adjust the animation later. Use Applied IK repeatedly to adjust the animation.

IK Solvers

Select an object in a hierarchy where you want IK to start. > Animation menu > IK Solver > Apply an IK solver. > Click the object in the hierarchy where you want the IK chain to end.

An IK solver creates an inverse kinematic solution to rotate and position links in a chain. It applies an IK Controller to govern the transforms of the children in a linkage. You can apply an IK solver to any hierarchy of objects. You apply an IK solver to a hierarchy or part of a hierarchy using commands on the Animation menu. Select an object in the hierarchy, choose an IK solver, and then click another object in the hierarchy to define the end of the IK chain.

Bones system with HI IK solver applied

Each type of IK solver has its own behavior and workflow, as well as its own specialized controls and tools that display in the Hierarchy and Motion panels. IK solvers are plug-ins, so programmers can expand the software's capabilities by customizing or writing their own IK solvers.

3ds Max ships with four different IK solvers.

How Does an IK Solver Work?

An IK solver generally operates in this way: an inverse kinematic chain is defined on part of the hierarchy, say from the hip to the heel, or the shoulder to the wrist of a character. At the end of the IK chain is a gizmo, called the goal. The goal can be repositioned or animated over time in a variety of ways, often using linkage, parameter wiring or constraints (page 2–392). No matter how the goal is moved, the IK solver attempts to move the pivot of the last joint in the chain (also called the end effector) to meet the goal. The IK solver rotates the parts of the chain to stretch out and
reposition the end effector to coincide with the goal.

Using an IK solver to animate an arm

Frequently, the end effector is constrained to the ground plane. For example, you might "pin" the toes as the heels lift in a character walk cycle. Then the movement of the root of the chain poses the legs up from the toes.

Four plug-in IK solvers ship with 3ds Max:

- **HI (History-Independent) Solver (page 2–446)**
  The HI Solver is the preferred method for character animation, and for any IK animation in long sequences. With HI Solvers, you can set up multiple chains in a hierarchy. For example, a character’s leg might have one chain from hip to ankle, and another from heel to toe.

  Because this solver’s algorithm is history-independent, it is fast to use regardless of how many frames of animation are involved. Its speed is the same on frame 2000 as it is on frame 10. It is stable and jitter-free in viewports. This solver creates a goal and an end effector (although the display of end effector is off by default). It uses a *swivel angle* (page 2–449) to adjust the solver plane to position the elbow or the knee. You can display the swivel angle manipulator as a handle in the viewport, and adjust it. HI IK also uses a preferred angle to define a direction for rotation, so the elbow or knees bend correctly.

- **HD (History-Dependent) Solver (page 2–461)**
  The HD Solver is a solver well-suited to use for animating machines, especially ones with sliding parts that require IK animation. It lets you set up joint limits and precedence. It has performance problems on long sequences, so it ideally use it on short animation sequences. It is good for animating machines, especially ones with sliding parts.

  Because this solver’s algorithm is history dependent, it works best for short animation sequences. The later in the sequence it is solving, the longer it takes to calculate a solution. It allows you to bind the end effector to a follow object, and it uses a system of precedence and damping to define the joint parameters. It allows for sliding joint limits combined with IK animation, unlike the HI IK solver, which only allows for sliding joint limits when using FK movement.

- **IK Limb Solver (page 2–472)**
  The IK Limb solver operates on only two bones in a chain. It is an analytical solver that is fast in viewports, and can animate the arms and legs of a character.

  The IK Limb solver can be used for export to game engines.

  Because this solver’s algorithm is history-independent, it is fast to use regardless of how many frames of animation are involved. Its speed is the same on frame 2000 as it is on frame 10. It is stable and jitter-free in viewports. This solver creates a goal and an end effector (although the display of end effector is off by default). It uses a *swivel angle* (page 2–449) to adjust the solver plane to position the elbow or the knee. You can target the swivel angle to another object to animate it. IK Limb Solver also uses a preferred angle
to define a direction for rotation, so the elbow or knees bend correctly. It also allows you to switch between IK and FK by keyframing IK Enabling, and it has a special IK for FK pose function so you can use IK to set FK keys.

- **Spline IK Solver (page 2–473)**
  The Spline IK solver uses a spline to determine the curvature of a series of bones or other linked objects.

  Vertices on a Spline IK spline are called nodes. Like vertices, the nodes can be moved and animated to change the curvature of the spline.

  The number of spline nodes can be fewer than the number of bones. This provides the ease of posing or animating a long multiple-bone structure with just a few nodes, as opposed to animating each bone individually.

  Spline IK provides a more flexible animation system than other IK solvers. Nodes can be moved anywhere in 3D space, so the linked structure can be intricately shaped.

  A helper object is automatically placed at each node when Spline IK is assigned. Each node is linked to its corresponding helper, so a node can be moved by moving the helper. Unlike the HI Solver, the Spline IK system does not use a goal. The positions of nodes in 3D space is the only factor that determines the shape of the linked structure. Rotating or scaling nodes has no effect on the spline or structure.

  **Note:** 3ds Max also provides two other methods of inverse kinematic manipulation of hierarchies, which don’t depend on a solver: Interactive IK (page 2–480) and Applied IK (page 2–481).

**IK with Bones**

While you can apply an IK solver to any hierarchy of objects, a system of Bones (page 1–404) combined with an IK solver is a good way to animate a character.

A bones system is a jointed, hierarchical linkage of bone objects. Bones are used as an armature on to which objects are linked. If you use the skin modifier (page 1–791), you can "skin" an object to the bones, so the animation of the bones deforms the mesh that models a character. If you have a jointed character, you can use linkage or constraints so the bones animate the mesh.

**Turning Other Objects into Bones**

Any object can be turned into a bone object. Right-click any object and select Properties from the quad menu (page 3–694). In the Bone group, choose Bone On/Off. You can then choose Show Links Only to replace the display of the objects with the bones. This can be useful if you have a geometrically intensive hierarchy to animate. The interactive viewport response will be much quicker.
when the geometry is hidden and displayed only at links.

You can display any object as a bone object. Select the object and then choose Bone Tools from the Animation menu. This opens the Bone Tools floater. On the Object Properties rollout, turn on Bone On. Then go to the Display panel, and on the Link Display rollout turn on Display Links and Link Replaces Object, which displays the bones instead of the object. This can be useful if you have a geometrically intensive hierarchy to animate. The interactive viewport response is faster when the geometry is hidden and displayed as links only.

Any object hierarchy can be displayed as bones.

Bones can scale, squash and stretch over time. See Using Objects as Bones (page 1–410).

Link Display

You can use Display Links and Link Replaces Object to display the links instead of the object.
These settings are found on the Link Display rollout on the Display panel. This can be useful if you have a geometrically intensive hierarchy to animate. The interactive viewport response is faster when the geometry is hidden and displayed only at links.

**Advantages of Animating Bones with IK**

It is possible to animate a character’s motion through forward kinematics, rotating each limb into position from the shoulder to the fingers, and the hips to the toes. But it’s a lot quicker and more realistic to use inverse kinematics to simulate the foot interacting with the ground. And it is a lot easier to control when you need to make changes to the animation. Rather than having keyframes on every bone in the chain, you have to make changes to only one node, to change the animation of the entire chain.

On the other hand, it is common for animators to use IK for the legs and FK for the torso and the arms. FK offers a bit more control for posing the upper body. It is not necessary to use IK for every character animation task. Using the HI IK solver allows you to jump back and forth easily between FK and IK.

**How to Apply an IK Solver**

You can apply an IK solver when you create a Bones system, or from the Animation menu:

- **Bones creation (page 1–404)**
  
  When you create bones, turning on the Assign to Children option lets you apply an IK solver immediately. Default=Off.

- You can apply the IK solver to a part of the skeleton using Animation menu > IK Solver. You must select the node where you want the IK chain to start, then choose Animation menu > IK Solvers and select the solver. Then click the node where you want the chain to end. The chain will be created between the pivot points of the two nodes. If you are using an IK Limb Solver, the IK goal will be placed two bones down from the highest node you’ve selected in the chain.

**Where to Adjust the IK Solver**

You adjust IK solver settings in the Motion and Hierarchy panels:

- **Motion panel (page 3–774)**
  
  When the goal of an IK chain is selected, the motion panel displays the rollouts for the individual IK solver.

- **HI Solver**—Motion panel parameters adjust the swivel angle (page 2–449) of the solver plane, to point the knees and elbows. Also, the controls in the IK Solver rollout let you mix periods of IK with FK (forward kinematics) through the Enabled button and the IK button.

- **HD Solver**—Motion panel parameters assign, remove, and edit the end effector for the currently selected joint. You can parent the end effector to another object, and return the skeleton to an initial pose. Changing IK controller parameters in the Motion panel affects the entire HD IK chain, even when you’ve selected only a single bone.

- **IK Limb Solver**—Motion panel parameters for the IK Limb solver are the same as for the HI Solver.

- **Spline IK Solver**—Motion panel parameters allow you to activate/deactivate the solver, adjust the bones assigned to the start and end joints, adjust start and end twist angles and make twist handle display settings.

- **Hierarchy panel (page 3–773)**
  
  When a bone is selected, the IK panel displays controls to activate and limit the rotational joints, and set a preferred angle for the joints. The preferred-angle poses of all the joints help control the direction of rotation of...
IK Solvers

the limbs. When a goal is selected, the IK panel is blank.

**HD Solver**—Select the end effector of an HD IK chain. In the Hierarchy panel, click IK. The controls that appear affect the HD Solver. You will also find the tools to bind to follow objects, and set precedence and joint limits, damping and spring back.

**IK Limb Solver**—When a bone is selected, the IK panel displays controls to activate and limit the rotational joints, and set a preferred angle for the joints. The preferred-angle poses of all the joints help control the direction of rotation of the limbs. When a goal is selected, the IK panel is blank. If you select a bone before applying an IK Solver, a different set of sliding and rotational joint parameters will be displayed, but these will be replaced once an IK Solver is applied.

**Spline IK Solver**—Select the spline of an Spline IK chain. In the Hierarchy panel, click IK. The controls that appear affect the Spline IK Solver. You will also find the tools to bind to follow objects, and set precedence and joint limits, damping and spring back. The controls in the IK panel are similar to the HD Solver.

**Procedures**

**To add an IK solver to a hierarchy or bones system:**
1. Create a bones system or any other linked hierarchy of objects.
2. Select a bone or an object where you’d like the IK chain to start.
3. Choose Animation menu > IK Solver, and then choose the IK solver:
   - HI Solver for character animation
   - HD Solver for mechanical assemblages with sliding joints
   - IK Limb Solver for two-bone chains
   - Spline IK Solver for improved control of intricate, multiple-bone structures
4. Click where you want the IK chain to end.
   If you are using the IK Limb Solver, you must apply the IK Solver to control only two bones.
   The IK solver appears in the viewport.

**To create a bones hierarchy that uses an IK solver:**
1. Go to the Create panel, choose Systems, and click Bones.
2. On the IK Chain Assignment rollout, choose an IK solver from the list.
3. Turn on Assign To Children.
4. Click and drag in a viewport to create the bones. Right-click to stop bone creation.
   The bones are created with the IK solver already applied.
   Note: If you use the Spline IK Solver, a Spline IK Solver dialog will open where you can make special settings for the spline and helpers used by the Spline IK solver.

**To display a hierarchy of objects as bones:**
1. Select the hierarchy of objects in the viewport.
2. From the Animation menu > Character submenu, choose Bone Tools.
   This Opens the bone Tools dialog.
3. Expand the Object Properties rollout.
4. In the Bone Properties group, turn on Bone On.
5. On the Display panel, scroll down to Link Display and expand it.
6. On the Link Display rollout, turn on Display Links, and Link Replaces Object.
   The objects disappear and the links are displayed as bones.
History-Independent (HI) IK Solver

The HI (History-Independent) Solver does not rely on IK solutions calculated in previous keyframes in the timeline, so it is just as fast to use at frame 2000 as it is at frame 20.

The HI Solver uses a goal to animate a chain. You animate the goal and the IK solver attempts to move the end effector (the pivot point of the last joint of the chain) to match the position of the goal. Often the goal is parented to other control objects such as points or dummies, splines or bones, and these control objects in turn are wired to viewport or rollout sliders.

The IK solution takes place in a plane, known as the *solver plane*. The angle of the solver plane in world space is controlled by a parameter called the *swivel angle* (page 2–449). The swivel angle is animatable. You can adjust it directly, or with a manipulator.

The HI Solver allows for the creation of multiple or overlapping chains. This allows you to create multiple goals for additional controls. By linking the goals to points, splines, bones or dummies, you can create simple controls to animate complex chains or hierarchies. You can also use constraints on these goals or control objects, as another animation tool.

Applying an HI Solver

To apply an HI Solver to any part of a hierarchy select the bone or object where you want to start. Then choose Animation menu > IK Solvers > HI Solver. In the active viewport move your cursor to the bone where you want the chain to end. When you click to select that bone, the goal is drawn at the pivot point of that bone. If you want a goal at the far end of the bone, refine the bone where you want to goal to be placed. An extra bone will be added, and then choosing that bone allows you place the goal at the end.

When you create bones, a small "nub" bone is automatically created at the end of the chain to assist in this process.

Setting Up Multiple Chains

To rig a skeleton for a human leg you could use three chains in one leg, as follows:

- The first chain is created from the hip to the ankle. This chain controls the overall leg motion including bending of the knee.
- The second chain is created from the ankle to the ball of the foot. This chain controls the heel’s up and down motion.
- The third chain is created from the ball of the foot to the toe.

When the three chains work together they help to maintain the foot’s position in space. This means it will keep the foot planted on the ground as the character’s body moves. All three IK chains in this hip-to-toe setup place goals at key positions in the foot that mimic natural foot behavior. In real life, the toe, ball of the foot, and heel can be planted on the ground or raised.

Each chain has an goal that drives motion on the heel, ball of foot, and toe. Use the IK goals to raise the heel, bend the toe, move and rotate the entire foot, and maintain the foot’s position in space.

Overlapping Chains

The IK solver system allows you to create overlapping IK chains in a single hierarchy. In a human leg, for example, you could create a chain running from the hip to the ankle, then a second chain from the knee to the ball of the foot, and a third from the ankle to the toes. Use overlapping chains, when you want to apply goals to sequential bones, but you don’t want to refine the bones.
Another good use for overlapping HI IK chains is to keep the goals at the bottom of the hierarchy firmly rooted in place. In the case of the leg example, the ankle, ball and toe of the foot would not move until the upper portion of the hierarchy had reached its full stretch.

Don’t try to overlap chains with different kinds of IK solvers or you might get unpredictable results.
Creating Control Objects

To create control objects to animate the goals, create dummies, points, splines or other objects near the goal, then link the goal to the control object. For example in a human leg, you might have a goal at the ankle, ball of the foot, and the toe. You then create three splines under the foot, one for the heel, one for the ball and one for the toe. Link each goal to each spline, then you can animate the goals using these splines. You could also link the splines together, so that the rotation of the toe is controlled by the movement of the heel.

Besides hierarchical linkage, you can now use the new Constraint system in conjunction with IK solvers. You could apply any of the constraints to create a relationship between the goals or bones and other objects. The goal could be position constrained to a dummy which is moved. Or you could create three bone chains that are all in the same place, and constrain one bone chain to another, then weight the constraints.

Bone chains constrained together

Using control objects gives you something bigger to select in the viewport. You can also use control objects to separate chains, for example in a human arm one chain could end at the wrist and another separate chain be created for the hand and fingers. The control object at the wrist serves as the root node for the hand chain, yet that chain would remain disconnected (hierarchically speaking) from the arm chain.

You can create viewport sliders using the manipulator helper, and then use the viewport sliders to control the transforms of the control objects. Use wire parameters (page 2–411) to hook up the sliders with the control objects. You can also create Custom Attributes to add these sliders to the object rollouts.

Mixing Forward Kinematics with Inverse Kinematics

The HI IK solver provides a tool for mixing FK and IK in a single animation track. There is an FK subcontroller beneath the IK controller assigned by this solver.

When the Enabled button is on, the FK subcontroller values are preserved but ignored. When Enabled is turned off, the FK subcontroller values apply. To access the Enabled button, select the goal and go to the Motion panel, then turn off the Enabled button. This will allow you to animate using FK rotations of the bones or hierarchy objects.

IK for FK pose allows one to turn on IK in middle of FK manipulation. When the Enabled button is turned off, and IK for FK Pose is on, then selecting and moving the goal lets you use IK to create the forward kinematic keyframes. Moving the goal poses the skeleton and add rotation keys to all the objects in the chain when the Auto Key button is on.

When working with IK and FK together it is possible to create a situation where the goal has moved away from the end of the chain. Use the IK/FK snap button to reposition the goal, snapping it back to the end of the chain. When AutoSnap is on, the snap happens automatically; when you touch the goal, you don’t have to click the IK/FK snap button.
Controlling HI IK Precision

When you are animating with HI Solvers, if you find the animation of the limbs is not smooth, you should try doubling the Iterations in the Solutions group of the HI Solver Properties rollout (page 2–456). You can also try reduce the Thresholds value to smooth the animation.

White Paper: Swivel Angle of the HI IK Solver

The fundamental requirement of HI Solver is that the solution be history-independent: the solution has to be based on the goal and other incidental parameters solely at their current states.

Swivel Angle Degree of Freedom

When the positional goal is given for a single chain, there remains an obvious degree of freedom: the rotation about the End Effector Axis (EE Axis). The swivel angle is used to describe this degree of freedom quantitatively.

Swivel Angle Degree of Freedom

When the positional goal is given for a single chain, there remains an obvious degree of freedom: the rotation about the End Effector Axis (EE Axis). The swivel angle is used to describe this degree of freedom quantitatively.

axis, the solver plane should be fixed. Therefore, the Zero Plane Map defines a vector field on a sphere. Given a point on the sphere, it produces a tangential unit vector to be interpreted as the normal to the zero plane.

1. Normal to the zero plane

Solver Plane Flipping

It is a mathematical fact that there does not exist a continuous vector field on a sphere. No matter how hard you try, there will always be a point on the sphere where neighboring vectors change dramatically. This is where the solver plane will flip when the end effector axis approaches to it.

This is because, on one hand, the history independent requirement demands us to assign a fixed vector to the singular point. On the other hand, no matter what vector is assigned, it will be dramatically different from some vectors assigned to the neighboring points.

Intrinsic Reference Frame for the Sphere

In order to define the Zero Plane Map, we need to define a reference frame for the sphere. This reference frame is intrinsic to the joint chain itself.

A sphere can be defined by the center, the horizontal plane, and the meridian (zero longitude). The center is assigned to the start joint.

The pose when all the joint angles assume preferred angles is particularly important. Let’s call it the preferred pose.

We use the solver plane at the preferred pose as the horizontal plane. Since the swivel angle is used to control the start joint, the preferred angles at the start joint are not so intrinsic. It is also reasonable to define the horizontal plane with the solver plane that is derived by assigning zeroes to the start joint and preferred angles to the other joints.

The EE axis defines the meridian. The sphere is now defined as shown in the following figure:

1. EE axis

All the joints assume preferred angles. The Zero Plane Map is to be defined on this sphere.

The API for the plug-in solver to define its own Zero Plane Map in fact takes the EE axis and the normal to the solver plane at the preferred pose:

```cpp
virtual const IKSys::ZeroPlaneMap*
GetZeroPlaneMap(const Point3& a0, const Point3& n0) const
```

where \(a_0\) and \(n_0\) are the EE axis and solver plane at the preferred pose, respectively. Object of ZeroPlaneMap is a function that assigns a plane normal to each point on the sphere.
Default Zero Plane Map

When not provided by plug-in solvers, (the IK Solver itself is implemented as a plug-in solver) the IK system will provide a default one. This map is defined by the following rules:

- **A**: For each point on the equator, the intersection of the horizontal plane and the sphere, the normal vector is defined as the vertical vector, pointing to the same direction as the normal of the solver plane at the preferred pose.

- **B**: For any point on the sphere other than the north or south poles, there is a great circle that passes the point and the north, south poles. This circle hits the equator at two points. One point is closer to the given point. The normal vector at the given point is defined as derived from moving tangentially the normal at the closer point on the equator along the great circle to the point.

Deriving the default normal to the zero plane

Normally, the preferred pose is the one when the solver is first assigned. So, the plane on which one lays the joints corresponds to the horizontal plane here. Rule A makes sure that the chain will stay on the plane if one moves the goal on the plane.

Rule B means that, when you move the goal along the great circle vertical to the equator, the chain will stay vertical, except when it passes through the poles, which are the singular points of this map.

Parent Space

So far, we have described things as if the whole world comprises only IK elements. In practice, the IK chain and goal might sit at points of separate transformation hierarchies. Ultimately, we need to map the position of the end effector that is described in the world to a point on the sphere. Depending how the sphere is mounted relative to the end effector position, the readings of latitude and longitude are different. The parent transformation space that this sphere is to be placed in is called the Swivel Angle Parent Space, or Parent Space when the context is clear.

The parent space has to be invariant with regard to the IK parameters. Right now, we provide two choices:

- **Start Joint**—The Swivel Angle Parent Space is the same as the parent space of the Start Joint.
- **IK Goal**—The Swivel Angle Parent Space is the parent space of the IK Goal.

Example 1

If both the start joint and the goal are rooted directly at the world, the choice of Parent Space does not give rise to any difference. In the following example, the start joint is parented to object A.
Chapter 12: Animation

The IK chain is parented (via the start joint) at object A.

Assume this is the pose when the IK solver is assigned. So, this is the preferred pose. The plane on that the joints are laid out is the horizontal plane of the (Zero Plane Map) sphere.

- **A**: Parent Space is Start Joint. In this case, the sphere is parented to A. If A is rotated about the drawn axis, the sphere is rotated together with it. The goal is in a separate transformation hierarchy. It stays in place, and the end effector sticks to it because of the IK solution. Since the (plane) normal is fixed to the sphere, it rotates with A, too. Therefore, the whole chain appears to be rotated together with the parent object.

- **B**: Parent Space is IK Goal. Suppose that the goal is parented to the world. In this case, the sphere is parented to the world and, hence, stays fixed. Since the normal is fixed to the sphere, the chain will appear stationary when A is rotated.

**Example 2**

In the following example, we look at a case where there exists a rotation in the parent space when the IK solver is assigned.

The parent space of the IK chain contains a rotation when the IK solver is assigned.

Parent A contains a rotation of 90 degrees. This is an abstraction of the case when a user creates four bones without an IK solver and later assigns an IK solver from Bone2 to Bone4. If we parent the chain directly to world, it would appear as shown in the right figure: the solver plane becomes horizontal.

- **A**: Parent Space is Start Joint. The sphere is mounted after the rotation of A and therefore the “horizontal plane” coincides with the chain plane as shown in the viewport. The singular points are perpendicular to the Start Joint with regard to the plane. When the goal/end effector is moved on the plane, it will never hit the singular points and flip.

- **B**: Parent Space is IK Goal. Again, we assume that the parent space of the goal is the world. The “horizontal plane” of the sphere becomes horizontal, as shown in the right figure. The singular points, the poles, are on the plane that joints are laid out. Therefore, when users move the goal/end effector left to right, or the other around, the end effector will move across the singular point and flip.

A problem of B is that the figure on the right is never shown to the user. They have to envision it in order to understand the flipping.
Example 3

This example describes what happened when Start Joint is reassigned. Suppose we have an IK chain of four bone nodes.

1. Bone01
2. Bone02
3. Bone03
4. Bone04

The Start and End Joints are Bone01 and Bone04, respectively. Suppose the pose shown in the figure is the preferred pose and Bone01 contains a rotation. If we parent Bone02 directly to the world, the hierarchy from Bone02 will appear as in the right figure.

When we reassign Start Joint to Bone02, the Zero Plane Map sphere will be based on the configuration on the right.

- **A**: Parent Space is Start Joint. In this case, the sphere that is fixed to the right configuration is to be parented to Bone01 together. This will be the same as the one based on Bone01 to Bone04. Therefore, we get the same normal and chain stays stationary.

- **B**: Parent Space is IK Goal. In this case, the sphere stays in the world while Bone02 is parented to Bone01. When Bone04 is moved to where it is shown on the left due to the transformation of Bone01, the observer who is fixed to the sphere that is fixed to the world will see that Bone04 moves away from the neutral position defined by the preferred pose. The algorithm then applies the Zero Plane Map to find the normal at the displaced position. It generally is not perpendicular to the viewport. Therefore, we will see a flip once it takes a new Start Joint.

If you delete the solver/goal and assigned a new one from Bone02 to Bone04, you will find that the chain won’t flip. Why? Assignment of Start Joint is different from creating a new IK chain/goal. Start Joint is one of many IK parameters. Reassigning it is simply the same as modifying any parameter. The rest parameters are intact. In particular, the Swivel Angle is not changed as a result of this reassignment.

Creating a new IK chain/goal is different. Effort is made to ensure that the joint chain stay fixed by adjusting parameters appropriately. In particular, the Swivel Angle will be set to a value so that the solver plane keeps stationary in the viewport.

---

**HI IK Solver Rollouts (Motion Panel)**

**IK Solver Rollout (HI Solver)**

Select an HI or IK Limb Solver IK Chain control (the blue cross at the end of the chain) > Motion panel > Parameters button > IK Solver rollout

The HI Solver is a history-independent solver that doesn’t rely on the calculations from previous frames for the IK solution, so it is fast to use no matter the length of your animation. The history-independent solver uses a goal to manipulate the end of the chain. It uses a preferred angle that specifies a preference regarding which direction the link will rotate: positive or negative.
Chapter 12: Animation

The preferred angle can also be considered as the initial angle; that is, the angle at which the link was rotated at the time the solver was applied.

The IK solution takes place in a plane, known as the solver plane. The angle of the solver plane is controlled by a parameter called the swivel angle.

The angle of the solver plane is actually calculated in one of two coordinate systems: the Start Joint Parent space or the IK Goal Parent space. World space is not an explicit option; however, you can easily configure the IK chain to work in world space by choosing the IK Goal Parent option and making sure that the IK goal is unlinked (i.e., has no hierarchical parent). In this case, the IK goal’s parent is the world, and therefore, the solver plane will be computed in world space.

The swivel angle is animatable. You can adjust it directly, or with a manipulator. Or you can target the swivel angle to an object and animate that to affect the swivel angle. These parameters are on the IK Solver Properties rollout (page 2–456).

The HI Solver is designed to let the animator jump back and forth between forward and inverse kinematics quickly and conveniently, with tools to automatically enable IK and snap the goal to the end effector.

**Procedures**

**To turn off IK on a chain:**

1. Select the goal of a chain with an HI Solver.
2. In the Motion panel IK Solver rollout, turn off Enabled.
   
   IK is now off, so you can select and rotate any of the objects in the chain. Turning IK on and off is animatable using the Auto Key button.

**To mix IK and forward kinematics (FK) in a single animation track:**

1. Apply an HI IK Solver to a hierarchy or bone system.
2. Turn on the Auto Key button and move the time slider ahead in time.
3. Select the goal of the IK Chain, and open the Motion panel.
4. Select and move the goal to animate the IK chain with Inverse Kinematics.
5. Advance the time slider again.
6. In the IK Solver Rollout, turn off Enabled and IK for FK Pose.
7. Select and rotate the root. The entire hierarchy rotates freely. You are now adding keyframes using forward kinematics.

**To match the goal and the end effector positions:**

1. If the goal and end effector become separated, click IK/FK Snap and the goal will move to match the end link of the chain.
2. If AutoSnap is turned on, clicking the goal will automatically perform the snap action, matching the goal and end effector positions.
Interface

IK Solver group

The items in this group provide the ability to set the start and end points of the selected HI IK solver chain. There are also controls in this rollout that allow you to use IK manipulation to create forward kinematic rotational keyframes on the hierarchy objects, and there are buttons to align the goal and the end effector.

**Solver field**—Allows selection of IK Solver. Choose between the HI IK Solver and the IK Limb Solver here. Any HI IK plug-in solver present at startup will appear in this list, as well.

**Enabled**—Turns IK control of the chain on and off.

The HI IK Controller has an FK subcontroller. When Enabled is selected, the FK subcontroller values are overwritten by the IK controller. When Enabled is turned off, the FK values are used. You can animate Enabled On and Off.

Use this to turn off the chain control by the goal, when you want to do forward rotations.

**IK for FK Pose**—Lets you turn on IK in middle of FK manipulation. When Enabled is off and IK for FK Pose is on, moving the goal will turn on IK automatically in the middle of an FK manipulation. The result of this is that all the FK subcontrollers receive values from the IK solution. Keys are placed on the hierarchy objects or the bones, not on the goal. When both Enabled and IK for FK Pose are turned off, moving the goal does not affect the chain at all.

**IK/FK Snap**—Performs an IK snap when in FK mode, and an FK snap in IK mode.

**IK Snap**—If the goal has moved away from the end of the chain, clicking IK/FK Snap moves the goal to coincide with the end link position.

**FK Snap**—The values of FK subcontrollers are suppressed by the solution of IK when IK is on (Enabled is on). Their values don’t always correspond to the current pose of the chain. If you turn off Enabled, the values of FK subcontrollers will suddenly take over. This can cause the chain to jump. FK Snap, before Enabled is turned on, forces the FK subcontrollers to assume values from the current pose (which is determined by the IK.) This eliminates the jump in the chain’s animation.

**Auto Snap**—When Auto Snap is on, the software automatically applies an IK/FK snap before you turn Enabled on or off. If Auto Snap is not on, you need to click IK/FK Snap before toggling Enabled, otherwise the chain will jump.

**Preferred Angles group**

**Set As Pref Angles**—Sets the preferred angle for each bone in the HI IK chain. The current parent-space rotation of each bone is placed into its X, Y, and Z Preferred Angle rotation channels as seen in the
Rotational Joint rollout of the Hierarchy|IK panel. This is useful for establishing a perfect match frame (page 3–969) when transitioning between forward and inverse kinematics.

Assume Pref Angles—Copies the X, Y, and Z preferred angle channels of each bone and places them into its FK rotation subcontroller. This essentially performs the inverse operation of the Set As Pref Angles function.

Bone Joints group
Allows you to change the ends of the IK chain.

Pick Start Joint—Defines one end of the IK chain. Select from the viewport or by name (press H).

Pick End Joint—Defines the other end of the IK chain. The direction of the chain is defined by the hierarchy, not by Start and End Joint. Select from the viewport or by name (press H).

Warning: If you change the Start or End Joints so the IK Limb Solver so there are more than two bones between the start and end, the solver will not work. Moving the IK goal does not affect the bones.

Tip: The order of the hierarchy determines the direction of the chain. You cannot reverse the direction of the chain by picking Bone 10 as the start and Bone 1 as the end.

IK Solver Properties Rollout (HI Solver)

Here are the additional controls for the HI IK solver. The IK Solver Plane is controlled here through the Swivel Angle, which can be animated directly or using a target object.

In the Parent Space group you can choose to whether the IK goal or the start joint will be used as the parent space for the swivel angle. If IK Goal is selected (which is the default), then the Swivel Angle of the chain is defined in the parent space of its goal. If Start Joint is chosen, then the Swivel Angle will be relative to the parent space of the start joint. These two options allow a much better control of the swivel angle on a chain with two HI IK solvers. For example, the first solver on the upper part of a chain can use a Swivel Angle in the Parent Space of the Start Joint, while the second IK solver on the lower part of the chain uses the Parent Space of the IK Goal. In this case, the change of the Swivel Angle for one chain won’t change the orientation of the other one.

In the Thresholds and Solutions group you can refine the IK solution. The Position Threshold sets a limit in units of how far the goal can be moved from the end effector, the Rotation does the same in angle degrees.

The Solutions group Iterations is the maximum number of attempts the IK solution will perform before giving up.

If your IK animation seems to jitter, try increasing the Iterations to 200. Increasing the Iterations will slow down the computational time, but should produce better results.

Manipulator for the Swivel Angle

You can adjust the swivel angle with the spinner in this rollout, or you can adjust it with a manipulator. To do so, turn on Select and Manipulate (page 2–15). The swivel angle manipulator is displayed as a handle in the viewports.
When you move the mouse over the manipulator, it turns red. At this point, you can drag the manipulator to change the swivel angle. The Auto Key button can be active while you do this.

You can also animate the swivel angle by using a target object. Pick an object for the target, then animating the object will animate the swivel angle.

The swivel angle manipulator is a standard plane angle manipulator (page 2–29). The HI Solver has its own controls for displaying this manipulator. These are on the IK Display Options rollout (page 2–458).

Procedure

To increase the precision of an IK solution:

1. Select the goal in an HI IK chain.
2. In the IK Solver Properties rollout increase the iterations to 200 in the solutions group.
3. Play or render the animation.
4. You can also adjust the Position and Rotation Thresholds to a smaller value.

Interface

IK Solver Plane group

Swivel Angle—Controls the Solver Plane which determines the direction of the knee or elbow in a human limb. The Swivel Angle can be manipulated in the viewport by turning on Swivel Angle Display in the Display Options rollout, and then turning on Manipulate Mode. When the swivel angle manipulator is displayed in the viewport, you can interactively animate the handle to animate the solver plane.

Pick Target—Lets you select another object to use to animate the Swivel Angle.

Use—Turns the use of the Target on and off.

Parent Space—Defines what space the Swivel Angle is relative to. Use this on chains with multiple solvers, so the swivel angle manipulations on one chain will not affect the second. For more
information, see *White Paper: Swivel Angle of the HI IK Solver* (page 2–449).

**IK Goal**—Defines the Swivel Angle parent space relative to the IK Goal.

**Start Joint**—Defines the Swivel Angle Parent Space relative to the Start Joint.

### Thresholds group

Use to define the tolerances the system uses for its calculations.

**Position**—Sets a limit in units of how far the goal can be moved from the end effector. Keep these numbers low.

**Rotation**—Sets a limit in degrees of how far the goal can be rotated away from the end effector rotation. Keep these numbers low for best results.

Note that adjusting the Rotation threshold on the HI Solver and IK Limb Solver has no effect. It is up to the plug-in solver’s discretion as to whether or not they will support a rotation component in the IK solution.

### Solutions group

Use to control the precision of the animation. Increase the iterations when the IK solution produces an animation that appears rough or jittered.

**Iterations**—The number of attempts an IK solution will make to find the best match between the goal and the end effector positions. Increase this number if you are seeing jumpy animation.

---

**IK Display Options Rollout (HI Solver)**

Create a bone chain > Add an HI Solver, > Motion panel

Here are the controls to turn on and off a variety of gizmos in the viewport. The Goal and End effectors, the vector handle of the swivel angle manipulator, and the IK solver display itself, are all located in this rollout.

### Procedure

**To see multiple IK solvers in a single chain:**

1. In a chain with multiple IK solvers, select a goal in the viewport.
2. In the IK Display Options rollout, turn on IK Solver Display Enabled.
3. Select a second goal and repeat the process.

   Each goal’s display remains on whether it is selected or not.

---

**End Effector Display group**

Controls the appearance of the end effectors in the IK chain. Off by default.

**Enabled**—Turns the end effectors display on or off.

**Size**—Controls the size of the end effector gizmo in the viewport.
Goal Display group
Controls the appearance of the goals in the IK chain. On by default.
- **Enabled**—Turns the goals display on or off.
- **Size**—Controls the size of the goal gizmo in the viewport.

Swivel Angle Manipulator group
Controls the display of the swivel angle manipulator in the IK chain. Default = on. Turn this on, then turn on Manipulate mode to see the swivel angle manipulator.
- **Enabled**—Turns the swivel angle manipulators on or off.
- **Size**—Controls the size of the manipulator’s handle in viewports.
- **Length**—Controls the length of the manipulator in viewports.

IK Solver Display group
Controls the appearance of the IK Solver display, the line drawn between the start and end joints. Turn this on when you have multiple chains that you want to see at the same time.
- **Enabled**—Turns on or off the IK Solver display.

---

**Sliding and Rotational Joints (HI Solver)**

Here are the controls for setting the joint limits when using the HI Solver. You can turn X, Y, or Z axes on or off, limit them, and set those limits here. This is also where the preferred angle is defined, and adjusted. The preferred angle defines the direction a chain will bend, which angle a chain will tend to rotate toward.

**Note:** Sliding joints are implemented in the HI Solver, but they do not take part in an IK solution. They do, however, take part during FK interactive manipulation.

Use the HD Solver if you need to animate sliding joints with inverse kinematics.

**Procedures**

**Example: To set the direction an IK chain will bend (preferred angle):**

To understand setting the preferred angle it helps to use a simple example.

1. Go to Create panel > Systems and turn on Bones.
2. Turn on Assign to Children and make sure the HI Solver is displayed in the Solver name field.
3. In the Top viewport, create a bone chain of four bones in a straight line.
4. Turn on the Auto Key button, and move the time slider to frame 50.
5. Select and move the goal so it is close to the root node.
6. Select any bone in the chain.
7. On the Hierarchy panel > IK panel, open the Rotational Joint rollout.
8. There are three axes. Find the one with the preferred angle that is not zero.
9. Change the preferred angle. If it is negative make it a positive one.
10. Play the animation, see how changing the preferred angle can redefine the direction of the rotation.

**To set rotational joint limits on a hierarchy of objects or a bone chain:**

1. Create a bone chain or a hierarchy of objects.
2. Select any object in the chain.

3. On the Hierarchy panel > IK panel, open the Rotational Joint rollout.

4. If you want to limit an axis, turn on Active and Limited, and set the values of From and To. The hierarchy will rotate in the viewport.

   Tip: Pressing the From and To labels instantly rotates the bone to those angles.

**Interface**

**Sliding Joints rollout**

**X, Y, Z Axis groups**

**Active**—Activates an axis (X/Y/Z). Allows the selected object to slide on the activated axis.

**Limited**—Limits the range of motion allowed on an active axis. Use in conjunction with the From and To spinners. Most joints are limited in their range of motion along an active axis. For example, a piston slides only within the length of its cylinder.

**From and To spinners**—Determine for position limits. Use in conjunction with the Limited function. Clicking the labels From and To moves the object to its limit position. Use this to check the sliding limits on an object.

**Rotational Joints rollout**

**X, Y, Z Axis groups**

**Active**—Activates an axis (X/Y/Z). Allows the selected object to rotate about the activated axis.

**Limited**—Limits the range of rotation allowed on an active axis. Use in conjunction with the From and To spinners. Most joints are limited in their range of rotation along an active axis. For example, a wheel rotating around an axle could be limited to rotate around only one axis.

**From and To spinners**—Determine for rotation limits. Use in conjunction with the Limited function. Clicking the labels From and To rotates the object to its limit rotation. Use this to check the rotation limits on an object.

**Preferred Angle**—Used by the HI Solver to set the initial pose for internal calculations. Determines the direction of rotation preferred by a bone.
History-Dependent (HD) IK

Select a node of hierarchy or bone chain. > Animation menu > IK Solvers > HD Solver > Click a second node of chain.

Animating with the HD Solver lets you use sliding joints combined with inverse kinematics. It has controls for spring back, damping, and precedence not found in the HI Solver. It also has quick tools for viewing the initial state of the IK chain. Use it for animations of machines and other assemblies. Since this is history dependent, performance is slower at the end of long animations. For lengthy scenes, use HI Solvers, if possible.

Animating the End Effectors

You animate a hierarchy of objects or bone structure using HD Solvers by animating special end effectors located at the bone joints. There are two types of end effectors: Position and Rotation. They are displayed as three intersecting blue lines at the joint.

When you select and transform a joint that carries either end effector, only the end effector itself is transformed. The objects or bones in the chain then use IK to calculate the IK solution.

Animating these end effectors is much like animating with Interactive IK except interpolation between keyframes uses correct IK solutions.

Linking End Effectors to a Parent

You can link HD IK end effectors to a parent to achieve results similar to using bound follow objects with Interactive and Applied IK. To link a HD IK end effector, you click Link on the Motion panel.

There are two reasons to link an end effector to a parent:

- You can rescale your entire hierarchy. If you animate a robot, and then later decide you want to scale the entire robot and its animation, link the robot’s root object to a dummy, link all of the robot’s end effectors to the same dummy, and then scale the dummy to scale all of the hierarchical objects as well as the animation of the end effectors.
- You can use linked end effectors for things like feet or hands. End-effectors are automatically bound to the world, so when you move a root object in your hierarchy, the end effectors remain behind. This is good for keeping feet on the ground, but not very good for hands, where you want them to move along with the character. To have hands follow the root object, link the end effectors of the hands to the root object.

Linking Bones to Follow Objects

You can also use follow objects instead of end effectors and bind bones to any number of follow objects using Interactive IK.

If you use follow objects with HD IK, you do not need to click Apply IK. The IK solver takes care of everything automatically.

See also

Inverse Kinematics Rollout (page 2–497)

Binding Objects (HD Solver)

Use the binding functions (page 2–492) in the HD Solver to cause an object to attempt to maintain its position and orientation relative to the world or to another object. A bound object will resist motion in the kinematic chain until the chain is stretched near its limits and the bound object must move to complete the IK solution.
Chapter 12: Animation

In the top row, the ball is independent of the lamp. In the bottom row, the lamp head is bound to the ball's position.

Setting Binding Options

You can bind an object by position, orientation, or both. Once an object is bound you can set binding axes, weight, and whether the binding is absolute or relative.

**Bind Position**—Causes an object to attempt to maintain its location or to match the location of a follow object.

**Bind Orientation**—Causes an object to attempt to maintain its rotational orientation or to match the orientation of a follow object.

**Relative**—Changes how an object reacts to a bound follow object. See the following discussion about binding an object to a follow object.

**Axis and Weight**—Set these options to control which axes are affected by the binding and the binding's influence over other bindings in the kinematic chain.

Binding an Object to the World

You can bind an object to the world if you want the object to hold its position and orientation as long as possible during IK operations.

If you are animating a walking figure you want one foot to remain in place while you position the other foot. Without binding, the whole hierarchy would have a tendency to slide around when you attempt to position a foot. Binding both feet to the world ensures that the unselected foot stays in place while you position the other foot.

Binding an Object to a Follow Object

You can bind a selected object in your hierarchy to any other object that is not a descendant of the selected object. This other object is called the follow object.

The behavior of the bound object varies depending on the state of the Relative buttons next to the bind options.

- **When Relative is inactive**, the bound object tries to match the exact position and orientation of its pivot point to the position and orientation of the follow object's pivot point.
- **When Relative is active**, the bound object mimics any changes in position or rotation of the follow object but does not try to match it exactly.

You might want to animate a figure that always points to another object. Bind the hand of the figure to the other object with Relative active. Turn IK on, and as you move the object, the hand and arm of the figure move to point at it.

Unbinding Objects

If you decide that you do not want an object to be bound you can either turn off the Bind Orientation and Bind Position boxes, or unbind the object from its follow object.

- If you turn off the binding options, you disable the effect of binding without removing the binding to a follow object. This method is handy if you decide to reposition a follow object after you have bound an object to it.
If you unbind an object, it permanently removes the binding to a follow object.

**Controlling IK Precision (HD Solver)**

Even with carefully defined joint precedence and joint parameters there are many valid IK solutions for any placement of an end effector. You set position and rotation thresholds to control IK precision and solution speed.

- The threshold and iteration settings are found on the Motion panel on the IK Controller Parameters rollout, when the end effector is selected.
- The threshold and iteration settings for the HD solver are also found on the Inverse Kinematics tab of the Customize > Preferences dialog.

**Position Threshold**—Sets how close the end effector has to get to the follow object or cursor position to be considered a valid solution. The value expresses a distance in the current unit system. Small values increase accuracy but take longer to solve.

**Rotation Threshold**—Sets how accurately the end effector has to match the orientation of the follow object to be considered a valid solution. The value expresses a rotation angle in degrees. Small values increase accuracy but take longer to solve.

**Iterations**—Sets the maximum number of times 3ds Max repeats the IK calculations to find a valid solution. A high Iterations value increases the chance that the software can calculate a valid solution, but takes longer to complete. The following rules apply:

- Calculations stop as soon as a valid solution is found, even if the maximum number of iterations have not been performed.
- The last solution calculated is used if the maximum number of iterations is reached, regardless of whether the solution satisfies the position and rotation thresholds.

**Setting Applied and Interactive Thresholds**

You set the threshold and iterations settings as a trade-off between accuracy and speed. You have two groups of settings so you can individually tune the behavior of applied IK and interactive IK.

- Use interactive IK if you want fast, real-time response. Your interactive IK preferences should be set for speed.
- Use applied IK if you want the solution to match the follow objects very closely. Your Applied IK preferences should be set for accuracy.

The default applied IK and interactive IK settings are shown in the following table:

<table>
<thead>
<tr>
<th>Thresholds</th>
<th>Applied IK</th>
<th>Interactive IK</th>
</tr>
</thead>
<tbody>
<tr>
<td>Position</td>
<td>0.100</td>
<td>1.000</td>

**HD Solver Motion Panel Rollouts**

To adjust the parameters for all bones or hierarchically linked objects in the chain, you select a single bone or object, and then adjust the parameters in Motion panel > Parameters to affect all the bones or objects in the hierarchy.

**Procedures**

See *History-Dependent (HD) IK Solver (page 2–461)*.
Chapter 12: Animation

Thresholds group

These settings are the same as those in Customize menu > Preferences > Inverse Kinematics. They set the threshold for the changes in position and rotation between the end effector and the last link of the chain.

Position—Specifies, in units, the "slop" factor between the end effector and its associate object. This is the allowable distance between the end effector and its object, given the current IK solution.

Rotation—Specifies the allowable number of degrees of rotational error between a rotational end effector and its associate object.

Solution group

Iterations—Specifies the maximum number of iterations allowed to solve the IK solution. The actual number of iterations used depends on the difficulty of the problem. This value simply puts a cap on it.

Start Time and End Time—Specifies the range of frames in which IK is solved. If the Start Time is set to 20 and the End Time is set to 80 in a 100-frame animation, and then the end effector is animated, the animation of the chain will only be correctly solved within the Start and End range.

Initial State group

When you first create a hierarchical chain, the initial position of the bones or objects is the initial state. The options here let you display, alter, or lock the initial state. When both of the options here are turned off (the default), transforming the end effector is different from transforming the other joints in the chain. When you select and transform a joint assigned an end effector, you are actually transforming the end effector, and an IK solution transforms the joints. This alters the position of the bones or objects in the viewport, but will not alter their initial state. On the other hand, when you select and transform any of the joints without end effectors, you alter their initial state.

Show Initial State—Shuts off the real-time IK solution. All objects in the chain are moved to their initial positions and orientations prior to any changes caused by IK calculations. The positions of the end effectors, however, are not affected.

Turn on Show Initial State to view the initial state, or adjust the initial state of bones or objects using end effectors. This is useful when you set joint limits using the IK controls in the Hierarchy panel: the joints jump to their limits while you set them. When Show Initial State is off (the default), you can select and alter the initial state of bones or objects without end effectors, but when you select a bone or object with an end effector, the end effector is transformed, leading to an IK solution; the initial state of the associate object is not changed. By selecting this, you can transform the initial state of the associated object.

Lock Initial State—Locks all bones or objects in the chain from direct transformations. You can, however, transform the end effector of any joint.
to generate the IK solution without altering the initial state. Activate this when you want to avoid accidentally selecting and transforming joints that are not assigned end effectors. When Show Initial State is selected, Lock Initial State is ignored.

**Update group**

The options in this group determine how the IK calculation is solved during the transformation of the end effector.

- **Precise**—Solves the entire chain precisely for all frames from the Start time to the current time. When you release the mouse button, the chain will not move. Since all frames must be solved from Start to current time, the solution takes longer if the current frame is 1000 rather than 100.

- **Fast**—Solves the chain only for the current frame while the mouse is moved. Releasing the mouse button solves for all frames. Although this is faster than Precise, sometimes the current-frame solution differs slightly from the all-frame solution. As a result, when you release the mouse, the objects in the chain might shift a bit.

- **Manual**—With this option, the IK problem is not solved until you click Update.

**Update**—With Manual on, click to solve the IK solution.

**Display Joints group**

The options here affect the display of the joint axes and limits. When a rotational or sliding joint is active (Active is selected in the Sliding or Rotational Joints rollouts in Hierarchy > IK panels), an orange "rod" appears representing the active axis. When the joint is also limited, a pair of small orange squares appears, representing the From and To limits of the joint. If it's a sliding joint, the squares are positioned on the axis rod. If it's a rotational joint, the squares are at the ends of an orange arc.

- **Always**—Displays the axis rod and joint limits for all joints in the chain at all times.

- **When Selected**—Displays the axis rod and joint limits only on selected joints.

Tip: The joint icons can be difficult to see when the bones are linked to mesh objects. When animating a bone-based hierarchy, you can hide all of the objects and display and animate only the bones, which makes the joint icons more visible. This is easily done by hiding geometry by category in the Display branch.

**End Effectors group**

With the options in this group, you can add or delete Position or Rotation end effectors for any joint. Options affect only the currently selected joint. An end effector is the object that the IK chain follows to come to a solution. There are two types of end effectors: Position and Rotation. Both are...
displayed as three intersecting blue lines at the joint. When you select a joint that carries either or both end effectors and perform a transformation matching the type of end effector, only the end effector itself is transformed. The objects in the chain then use IK to follow and create the IK solution.

When you transform a joint that does not have an end effector (or perform a type of transform that doesn’t match the assigned end effector), you transform the joint itself and alter its initial state.

**Position**—Creates or deletes Position end effectors. If the node already has an end effector, only the Delete button is available.

**Create**—Creates a Position end effector for the selected node.

**Delete**—Removes the Position end effector from the selected node.

**Rotation**—Works like the Position buttons, except Rotation end effectors are created rather than Position end effectors. When you want to solve for IK rotation, add a Rotation end effector, and then use the Rotate tool to rotate the end effector.

**End Effector Parent**—Links an end effector to another object in the scene. Since end effectors are not, in themselves, objects, you won’t see this linkage in Track View, but the linked end effector will inherit the transformations of its parent.

**End Effector (Display)**—Displays the name of the selected parent object.

**Link**—Makes a selected object a parent of the currently selected link.

**Unlink**—Unlinks the currently selected end effector from its parent.

**Remove IK group**

**Delete Joint**—Deletes any selection of bones or hierarchical objects. Doesn’t delete the IK; only the selected hierarchical members.

Note: Using the DELETE key will delete the entire hierarchy.

**Remove IK Chain**—Deletes the IK Solver from the hierarchy. Doesn’t delete the objects or bones, only the IK controls.

**Position**—Displays the Key Info parameter rollouts specific for a Position end effector. This option is not active if no Position end effector is assigned. (The Key Info parameters are the same as those used for any Position controller.)

**Rotation**—Displays the parameters for an assigned Rotation end effector. This option is not active if no Rotation effector is assigned. (The Key Info parameters are the same as those used for any Rotation controller.)

---

**HD Joint Settings**

You control a joint’s resistance to motion, and its tendency to return to its original position, by setting Ease, Damping, and Spring Back options.
Easing a Joint at Its Limits

An organic joint, or a worn mechanical joint, moves freely in the middle of its range of motion but moves less freely at the extremes of its range. Use Ease to cause a joint to resist motion as it approaches its From and To limits.

For example, your forearm might move freely in the middle of its range of motion, but it resists movement when you try to squeeze it against your upper arm or extend it all the way out. Ease simulates this effect.

Damping Joint Action

As a joint corrodes, dries out, or is put under a heavy load, it resists motion along its active axes. Damping simulates the natural effect of joint friction or inertia. Enter a value greater than zero in the Damping field to apply resistance over a joint’s full range of motion.

As damping increases a joint resists motion and other joints are required to move more. A damping value of 1.0 means there is extreme resistance and a joint will not move on that axis.

For example, a telescope with no damping at all allows each cylinder to move to its maximum limit before the next cylinder moves. If the cylinders have damping values assigned, then each cylinder causes its parent to begin moving before it reaches full extension.

Setting a Joint to Spring Back

When a joint resists motion, it also has a tendency to return toward its at-rest position. You simulate this by setting Spring Back tension in the joints. As the joint moves further from its rest position, an increasingly larger force pulls the joint back, like a spring.

When you set Spring Tension higher, the spring pulls harder as the joint moves farther away from its rest position. Very high settings can turn the joint into a limit, because you can reach the point where the spring is too strong to allow the joint to move any farther.

Using Default Joint Precedence (HD Solver) (page 2–468)

Choosing Child-to-Parent Precedence (HD Solver) (page 2–469)

Choosing Parent-to-Child Precedence (HD Solver) (page 2–470)

Setting Precedence Manually (HD Solver) (page 2–471)

Terminating Chains (HD Solver) (page 2–471)
Chapter 12: Animation

The hoof (a child) has precedence over the leg (its parent).

For any given position of an end effector, there are many possible IK solutions.

The three joint precedence controls in the Object Parameters rollout are:

- **Precedence**—Sets joint precedence manually.
- **Child->Parent**—Automatically sets joint precedence to decrease in value from child to parent.
- **Parent->Child**—Automatically sets joint precedence to decrease in value from parent to child.

**Determining Order of Calculations**

You control the HD IK solution by setting joint precedence to determine which joints contribute the most to the HD IK solution and which joints contribute the least.

- Joints with high precedence values are calculated first, and contribute more motion to the HD IK solution.
- Joints with low precedence values are calculated last and contribute the least motion to the HD IK solution.
- Joints with equal precedence values are calculated by order in the hierarchy. Joints closer to the end effector are calculated first and joints closer to the root are calculated last.

Of all of the joint parameters, Joint Precedence is the most subtle.

**See also**

- Using Default Joint Precedence (HD Solver) (page 2–468)
- Choosing Child-to-Parent Precedence (HD Solver) (page 2–469)
- Choosing Parent-to-Child Precedence (HD Solver) (page 2–470)
- Setting Precedence Manually (HD Solver) (page 2–471)

**Using Default Joint Precedence (HD Solver)**

The default joint precedence is suitable for many HD IK solutions. It assumes that joints closest to where a force is applied (the end effector) will move more than joints farther from the force.

The default joint precedence is a value of 0 for every joint: *all joints have the same precedence value*. This default starts calculations with the end
Choosing Child-to-Parent Precedence (HD Solver)

effector and progresses up the IK chain until the base object is reached.

Using methods described in the following topics you can change the default precedence values. You can also set your kinematic chain back to its default precedence.

To reset the default joint precedence:
1. Select all objects in the kinematic chain.
2. On the Hierarchy panel, expand the Object Parameters rollout.
3. Set Precedence to 0.

Note: Default joint precedence occurs whenever all joints in the kinematic chain have the same precedence value. Assigning a value of 100 to all objects in the kinematic chain is exactly the same as assigning a value of 0.

Choosing Child-to-Parent Precedence (HD Solver)

Child->Parent precedence causes joints closest to where a force is applied (the end effector) to move more than joints that are farther away from the force. Like the default precedence, Child->Parent precedence produces a natural result that is suitable for many IK solutions.

The first figure shows values for child-to-parent precedence.

Assigning Child->Parent Precedence

Clicking Child->Parent sets joint precedence based on a child having a higher precedence than its parent. The values are calculated by setting the root of the entire hierarchy to a precedence value of 0 and each child to a value equal to 10 times its depth from the root.

You almost always assign Child->Parent precedence to an entire kinematic chain. The chain for the structure in the figure uses the body as the root object and the duck as the end effector.

Each object receives a value equal to its depth from the root of the hierarchy times 10. Note that precedence value calculation is based on the root of the hierarchy whether or not the root is selected as part of the kinematic chain.
You might want to assign Child->Parent precedence to just a single object in the kinematic chain. For example, if you have been manually changing precedence values, you might want to set an object to its original Child->Parent value. The value assigned to the object is equal to its depth from the root of the hierarchy times 10.

Choosing Parent-to-Child Precedence (HD Solver)

Parent->Child precedence causes joints closest to where a force is applied (the end effector) to move less than joints farther away from the force. This is the opposite of Child->Parent precedence. Parent->Child precedence assigns the highest precedence to the base object and the lowest precedence to the end effector.

You might use this type of precedence for a number of special cases. For example:

- When joints near the end effector are less flexible than joints near the base. You use Parent->Child precedence in conjunction with limits and damping. For more information about the latter two, see Setting Joint Resistance and Spring Back (page 2–466).

- When animating a kinematic chain where the real-world object is moved by applying force to the base of the chain. Imagine an animal’s tail. Using IK you animate the tail by moving the tip of the tail. However, a real animal moves its tail using muscles at the tail’s base. The real-world motion is applied from the base to the tip in a Parent->Child order.

Assigning Parent->Child Precedence

Clicking Parent->Child sets joint precedence based on a child having a lower precedence than its parent. The values are calculated by setting the root of the entire hierarchy to a precedence of 0 and each child to a value equal to -10 times its depth from the root.

You almost always assign Parent->Child precedence to an entire kinematic chain. The chain for the structure in the above figure uses the body as the root object and the duck as the end effector. Using Parent->Child precedence, the feet are assigned a precedence of -50 and the duck is assigned a precedence of -140.

You might want to assign Parent->Child precedence to a single object in the kinematic chain. The value assigned to the object is equal to its depth from the root of the hierarchy times -10.
Setting Precedence Manually (HD Solver)

Some models and animated motions don’t fit neatly into a Child->Parent or Parent->Child precedence. In such situations you can manually assign precedence values to any object in the IK chain on a joint-by-joint basis. For example:

- Animating models with a combination of light, flexible joints and heavy, resisting joints. Imagine a model of heavy iron balls linked together with lengths of chain. Setting the precedence values of the chains higher than the precedence values of the iron balls simulates the balls’ inertial resistance to motion.

- Animating a motion where certain joints must move before other joints. Imagine a golfer’s arm where the elbow should remain locked while swinging a golf club. You could accomplish this by setting the precedence of the elbow lower than the precedence of the wrist and shoulder.

High precedence values are calculated before low precedence values. Precedence values that are equal are calculated in Child->Parent order.

The precedence calculations only consider the relative IK values. This means that an IK chain of three objects with precedence values of 0, 30, and 200 would have the same solution if the precedence were changed to 1, 2, and 3.

Terminating Chains (HD Solver)

The kinematic chain is automatically defined using the object you select as the end effector and working up the hierarchical tree to use the root object as the base of the kinematic chain. Sometimes you might not want the kinematic chain to go all the way to the root of the hierarchy. This is especially true when you are animating multi-limbed or branching structures, such as an octopus or a tree.
You use the Terminator option in the Object Parameters rollout to stop calculation of the kinematic chain before it reaches the root object of the hierarchy. A terminator object stops calculation at the terminator’s child object; the terminator itself is not affected by the IK solution. This gives you very precise control over the behavior of the kinematic chain.

For example, look at the bird in the figure. The bird is linked with its body as the root of the hierarchy. If you use inverse kinematics to move the duck, all objects from the duck to the body will be affected by the IK solution. However, if you define a neck bone as a terminator object, then only the objects from the duck to the neck vertebrae are affected.

**IK Limb Solver**

The IK Limb solver is specifically meant for animating the limbs of human characters; for example, the hip to the ankle, or the shoulder to the wrist. Each IK Limb solver affects only two bones in a chain, but multiple solvers can be applied to different parts of the same chain. It is an analytical solver that is very fast and accurate in viewports.

To use the IK Limb solver, a bones system must have at least three bones in the chain. The goal is placed at the pivot point of the bone that is two bones away from the first selected bone.
The IK Limb solver works not only with bone hierarchies, but with any linked hierarchy that has at least three elements, and is set up to model a human limb. The additional requirements are:

- The first joint is "spherical." That is, it has three degrees of freedom.
- The second joint is "revolute," a robotics term that means it is based on a pin and has one degree of freedom.

The IK Limb solver uses the same controls as the HI Solver, so it allows for mixing periods of forward and inverse kinematics in the same animation period. It does not use the HD Solver methods of damping, precedence, and setting joint limits, instead it has a preferred angle parameter, swivel plane and IK/FK Enabling.

The IK Limb solver can be exported directly to a game engine.

**Procedures**

**To apply a IK limb solver:**
1. Create a chain that has three bones.
2. Select the root of the chain.
3. From the Animation menu, choose IK Solvers > IK Limb Solver.
4. In the viewport, move the mouse. You will see a dotted line attached to the cursor as you move the mouse.
5. Click the third bone in the chain, or any bone after the third bone.

The IK Limb solver displays on the bone chain. The IK Limb solver only affects two bones in the chain, but you need to select the third bone to put it on the other two bones.

**To animate an IK limb solver chain:**
1. Apply the IK Limb solver to a two bone chain, with joint limits as described above.
2. Select the goal.
3. Move or rotate the goal.

**Interface**

The Interface for the IK Limb solver is identical to that of the HI Solver.

Select the goal at the end of the chain, and open the Motion panel. Here you will see the controls for the IK Limb solver. (The fourth is available from the Hierarchy > IK panel when a bone is selected.)

---

**Spline IK**

Animation menu > IK Solvers > Spline IK Solver

Create panel > Systems > Bones > Choose SplineIKSolver from the IK Solver list.

The Spline IK solver uses a spline to determine the curvature of a series of bones or other linked objects.
You can move and animate the spline vertices to change the curvature of the spline. Usually, a helper is placed at each vertex to assist in animating the spline. The spline curvature is then passed on to the entire linked structure. The bones themselves do not change shape.

Normally the number of spline vertices and bones are the same, but you can use fewer vertices for easier posing and animating a long multiple-bone structure with just a few nodes, as opposed to animating each bone individually.

Spline IK provides a more flexible animation system than other IK solvers. You can position vertices/helpers anywhere in 3D space, so the linked structure can assume any shape you want to give it.

A helper object is automatically placed at each vertex when Spline IK is assigned. Each vertex is linked to its corresponding helper, so a vertex can be moved by moving the helper.

Unlike the HI Solver, the Spline IK system does not use a goal. The positions of helpers/vertices in 3D space is the only factor that determines the shape of the linked structure.

Note: Moving the Spline IK helpers to curl the spline can sometimes cause bones to rotate or flip unexpectedly. If this happens, you can try choosing a different upnode object with the IK chain's Pick Upnode option in the IK Solver Properties rollout (see Spline IK Solver Rollouts (page 2–478)), or use a different IK method for your hierarchy.

Applying a Spline IK Solver

The Spline IK solver can be applied at the time bones are created, or after the bone structure has already been made.

To apply a spline IK solver when bones are created:
1. Choose Create panel > Systems > Bones.
2. On the IK Chain Assignment rollout, set IK Solver to SplineIKSolver, and turn on both check boxes: Assign To Children and Assign To Root.
   By default, Assign To Root is on automatically when you turn on Assign To Children.
3. Draw the bone structure as usual. When you right-click to end the bone creation process, the Spline IK Solver dialog (page 2–477) appears. Set parameters and click OK.
This procedure automatically draws the spline based on your dialog selections and sets up the Spline IK system to work with the spline. The software automatically assigns a Path constraint to the root bone to constrain it to the helper/vertex at that end of the spline.

**To apply a Spline IK solver to an existing bone structure:**

1. Create a bone structure without an IK chain.
2. Draw a spline or NURBS curve to be used by the bones. The curve can have any length and shape, and does not have to match the length or shape of the bone structure.
3. Select the bone or object where you want the chain to start.
4. Choose Animation menu > IK Solvers > Spline IK Solver. In the viewport, move the cursor to the bone or object where you want the chain to end and click that bone. Then move the cursor to the spline and click it.
Chapter 12: Animation

The bone structure jumps to the spline and takes its shape, and a helper is created on the spline at each vertex. A Path constraint is automatically assigned to the root bone to constrain it to the helper/vertex at that end of the spline.

4. Create a spline or NURBS curve to be used with the Spline IK system. It is recommended that you apply the Spline IK Control modifier (page 1–830) to it and then click Create Helpers to place helpers at each vertex, making the spline easier to control.

5. Select the IK chain cross hairs and access the Motion panel. On the Spline IK Solver rollout, click Pick Shape and click the spline. With this method, the position constraint is not automatically assigned to the root bone, so it must be assigned manually.

6. Select the root bone. Choose Animation menu > Constraints > Path Constraint, and then click the spline. This moves the bone structure to the spline, if they’re apart, and creates a Position List controller for the bone with the Path Constraint as the second (active) constraint.

Note: This also animates the bones along the path. If you don’t want this, delete the second animation key.

Working with the Spline IK Solver

To use the Spline IK Solver, move the helpers to shape the spline. Do not move the spline. The shape of the spline is determined by the positions of the vertices, so moving the spline itself has no effect on the bone structure. If the spline is moved, it will snap back to the helpers the next time a helper is moved. However, it is recommended that you not move the spline at all.

Once you have finished setting up the spline IK solver, it can be helpful to freeze the spline to avoid accidentally moving it.

Moving helpers changes the shape of the spline. To twist the spline, select the spline IK chain object and go to the Motion panel to change twist angles in the IK Solver Properties rollout.
Spline IK Solver Dialog

Create menu > Systems > Bones > Choose SplineIKSolver as IK Solver and turn on Assign To Children. > Create bone structure.

The Spline IK Solver dialog appears after bone creation if the Spline IK Solver has been selected as the IK solver and Assign To Children is turned on.

This dialog sets parameters for the spline that will be created to control the bone structure. The spline, in turn, is shaped by the positions of helper objects at each knot (control point).

See also
Spline IK Solver Rollouts (page 2–478)

Interface

Spline Options group

IK Name—Sets the name of the IK chain object. This object appears as a set of blue cross hairs at the end of the chain after you click OK.

Auto Create Spline—Automatically creates the spline used for the Spline IK solver based on the parameters on this dialog. When off, no spline is created and a spline must be manually created and assigned to the spline IK solver in order to use the solver. See Animating with the Spline IK Solver (page 2–473) for a description of this procedure. Default=on.

Curve Type—Choose the type of curve to serve as the Spline IK control:

- **Bezier**—Creates a Bezier spline, similar to a spline created with the Create > Shapes > Line tool. This is the default curve type.
- **NURBS Point**—Creates a NURBS Point Curve, where all knots (control nodes) lie on the curve.
• **NURBS CV**—Creates a NURBS CV Curve, where knots (control nodes) do not necessarily lie on the curve.

**Number of Spline Knots**—Vertices on the spline, or control points and CVs on the NURBS curve. You alter the spline or curve by moving and animating the knots. The number of knots sets the degree of refinement on the curve as well as the number of points that can be selected and moved to change the shape of the curve.

The default value is the number of bones in the Spline IK chain. Because one purpose of a Spline IK solver is to reduce the number of objects that require animation, you might want to use a lower value, such as half the number of bones.

**Helper Options group**

**Create Helpers**—When on, the software places one or more Point helper (page 2–23) objects at each knot in the spline or curve, making it easier to move and animate the knots.

You can enable more than one type of helper. When you move one helper, the others at the same location also move, as does the curve knot.

**Center Marker**—Places a small X-shaped Point helper at each knot.

**Axis Tripod**—Places a small tripod-axis-shaped Point helper at each knot.

**Cross**—Places a small cross-shaped Point helper at each knot.

**Box**—Places a small box-shaped Point helper at each knot.

**Size**—Sets the size for helpers.

**Constant Screen Size**—Keeps the sizes of helpers constant regardless of the zoom extent of the viewports.

**Draw On Top**—Displays the helpers on top of all other objects in the scene for improved visibility in busy scenes.

**Tip:** To change the display of helpers after creation, select each helper and change selections on the Modify panel.

*Spline IK* (page 2–473)

---

### Spline IK Solver Rollouts

When a Spline IK chain is selected, the options on the Motion panel can be used to change the starting and ending bones, and twist angles for the entire linked structure.

To create a Spline IK Solver, see *Animating with the Spline IK Solver* (page 2–473).

### Interface

*Spline IK Solver rollout*

- **Spline IK Solver**
  - **SplineIK Solver**
    - **Enabled**
    - **Pick Shape:**
      - SplineIKNode01
  - **Bone Joints**
    - **Pick Start Joint:**
      - Bone01
    - **Pick End Joint:**
      - Bone07
The options on this rollout allow you to pick a new spline for the spline IK chain, or pick new start and end joints for the chain.

**Spline IK Solver group**

**Spline IK Solver**—Displays the name of the solver. The only available solver is Spline IK Solver.

**Enabled**—Turns control of the solver on and off.

**Bone Joints group**

**Pick Start Joint**—Picks the start joint for the Spline IK Solver and displays the object name.

**Pick End Joint**—Picks the end joint for the Spline IK Solver and displays the object name.

**IK Solver Properties rollout**

The options on this rollout set the start and end twist angles for the spline IK chain. The twist manipulators on each end of the chain show the degree of twist.

**Twist Start Angle**—Sets the twist angle for the entire chain, rotating all bones in the chain.

**Twist End Angle**—Sets the twist angle for the end joint relative to the start joint, creating a gradual twist over the entire chain.

**Pick Upnode**—When Spline IK is assigned to a bone chain, the IK system attempts to determine the “up” direction for bones, which is the direction in which the bones’ back fins should point. The Spline IK Solver might interpret this direction incorrectly, causing bones to flip to one side or the other. Picking an upnode causes the “up” direction to point along the picked object’s local Z axis. By default, the upnode is set to the first helper/knot on the spline, which usually causes the “up” direction to be interpreted correctly.

**Use**—Use the picked node to specify the “up” direction for the root bone.

**IK Display Options rollout**

The options on this rollout set the display of twist manipulators and the IK chain object.

**Twist Start group**

**Enabled**—Turns on the display of the start twist manipulator. Default=on.

**Size**—Sets the size of the start twist manipulator. Default=1.0.

**Length**—Sets the length of the start twist manipulator. Default=75.0
Chapter 12: Animation

Interactive and Applied IK

Animating with Interactive IK

With Interactive IK and the Auto Key button turned on, you position your model on keyframes, and the IK solution is interpolated between those keyframes. Because the IK solution accounts for multiple objects and the joints between objects, the interpolated animation of an IK object is usually different from the animation of objects without IK.

Tip: Interactive IK is a feature carried over from the earliest version of the software. It is recommended that you explore the IK Solver methods first, and only use Interactive IK if you find the IK Solvers will not satisfy your needs.

Example of Interactive IK

The following example demonstrates how an interactive IK animation works and how it might differ from what you expect. The figure shows an IK structure with its end effector resting on top of a box. The box moves in a straight line over 100 frames.

Turn the Auto Key button on and then in the Hierarchy panel > IK tab, turn on Interactive IK. Move the end effector of the IK structure to rest on top of the box at frame 100. The interpolated animation of the end effector follows a natural looking curved path.

You might have expected the IK bone structure to follow the same path as the box. However, the IK solution is only calculated at the keyframes. The positions and rotations of all the objects in the kinematic chain are interpolated between the keyframes to produce the curved result.

To make the end effector closely follow the path of the box, you would have to add more keyframes. You can also use binding and standard applied IK. For information about making the end effector precisely follow the motion of the box, see Animating with Applied IK (page 2–481).
Behavior of Objects in IK Mode
As you move and rotate objects using interactive IK you notice that some objects might not be able to move or rotate about all axes. This is because the objects are constrained by the joint parameters you have set. If the joint parameters specify that motion cannot occur in a certain axis, the end of the chain will not move.

Behavior of Root Objects in IK Mode
An option on the Inverse Kinematics panel (page 3–830) of the Preference Settings dialog enables the special case of moving and rotating root objects when IK mode is on. The name of this control is Always Transform Children Of The World.

While you are transforming an end effector using IK mode, the settings for the root object’s joint parameters are used and the root object does not move with respect to the World. If you select the root object, its joint parameters are released and you can transform the root object.

If you decide you want root objects to always use their joint parameters, you can turn off the Always Transform Children Of The World option.

Single, unlinked objects are hierarchies of one. An unlinked object is its own root and is also a child of the World. Turning Always Transform Children of the World will prevent you from transforming single objects in IK mode.

Animating with Applied IK
Select the end of a hierarchy > Hierarchy panel > IK > Set object parameters such as Bind to Follow Object > Apply IK.

Applied IK requires you bind one or more parts of your IK structure to animated follow objects. Once bound, you can select any object in your kinematic chain and click Apply IK. This calculates the IK solution for each frame of the animation and places transform keys for every object in the IK chain.

The Apply IK method of animation works best when you want objects in the kinematic chain to match the motions of other objects exactly.

Tip: Applied IK is a feature carried over from the earliest version of the software. It is recommended that you explore the IK Solver methods first, and only use Applied IK if you find the IK Solvers won’t satisfy your needs.
Example of Applied IK

The illustration demonstrates how an applied IK animation works. Just as in the example in *Animating with Interactive IK* (page 2–480), the figure shows an IK lamp structure with its head positioned over a spider. To maintain the offset distance between the lamp head and spider, the actual end effector is an invisible Dummy helper object, placed within the spider and linked to the lamp head as a child. The spider moves in a straight line over 100 frames.

To bind the end effector to the spider, click Bind, and then drag a line between the two. Once the end effector is bound to the spider, it will try to match the location of its pivot point with the pivot point of the spider.

Select the end effector and click Apply IK. The software matches the end effector with the box and calculates the IK solution for every frame. Playback of the animation shows that the end effector perfectly follows the box.

Note: In the above example, the end effector is an invisible Dummy helper object, which is used to maintain the offset distance between the lamp head and the spider.

Clearing Keys from Previous Animation

If you have animated any members of the IK chain interactively, or run Apply IK previously, the existing animation keys will affect the new IK solution. Sometimes that is exactly what you want. You can use manual animation to subtly nudge the IK solution toward a particular result. However, it is more likely that you want to remove old keys in order to begin the IK calculations with a clean slate.

The Clear Keys option in the Inverse Kinematics rollout controls whether or not old move and rotate animation keys are removed.

Constraining the IK Solution to Specific Frames

You use the Start and End fields in the Inverse Kinematics rollout to set the range of frames used to calculate the applied IK solution. Using these fields, you can restrict IK solutions to specific frames and solve for different solutions in different time segments.

You can set the Start and End fields to include frames outside of the active time segment.

You can also constrain an IK solution to frames where a key exists for an end effector. This is useful if you want to animate a hierarchy using end
effectors but do not want keys generated on every frame.

Turn on Apply Only To Keys to constrain the IK solution to frames with end effector keys.

**Watching Progress of the IK Solution**

Normally, Apply IK calculates all frames before updating the viewports. To watch the progress of Apply IK frame by frame, turn on Update Viewports on the Inverse Kinematics rollout.

Updating the viewports greatly slows down the Apply IK process but it can help you troubleshoot complex animations.

---

**Joint Controls**

**Setting Joint Parameters**

You set whether a joint behaves as a hinge, a drawer slide, or another type of joint by setting joint parameters (page 2–459) for each object in the kinematic chain. Joints control the rotation and position of an object with respect to its parent.

Any object has a maximum of two joint-type rollouts: One rollout contains settings to control the object’s position, and the other controls the object’s rotation. There can be many different types of positional and rotational joints. Which joint parameters are available is determined by the type of IK solver assigned to an object. HI Solvers, for instance, are controlled with a preferred angle setting found in the Rotational Joint parameters. HD Solvers have additional parameters for spring back, precedence, and damping, not found in the HI Solver.

Any hierarchy of object or bone systems can have its joint limits defined. Select all the objects, and turn on their bone or link display. Select the bone or link and open the Hierarchy panel > IK tab. Scroll down to the Sliding and Rotational Joints. There, you can activate axes and set their individual limits.

Note: Different IK solvers use different joint limits. When using a bone system, add the IK solvers first, then set the joint limits second.

**Common Joint Types**

The most common joint types are Rotational and Sliding joints. Other common joint types are Path and Surface joints. Each joint type displays its own set of joint parameters.

**Rotational joints**—Control rotation of objects using many of the standard rotation controllers. The parameters for rotational joints set an object’s ability to rotate about a given axis.

For many IK structures, consider using an Euler XYZ controller (page 2–318). Quaternion-based controllers tend to freeze if an object is moved beyond rotational joint limits before turning on IK.

**Sliding joints**—Control the position of objects using many of the standard position controllers. The parameters for sliding joints control whether an object can move along a given axis.

**Surface joints**—Control the position of objects using Surface constraint (page 2–396). The parameters control how the object travels along its assigned surface.

**Path joints**—Control the positional motion of objects using Path constraint (page 2–398). The parameters for path joints control how far an object can travel along its assigned path.

**Using Joint Parameters**

The way the children behave toward one another is governed by the inheritance of the transforms
down the chain. Setting joint limits on individual child objects can influence this inheritance. If three children in a row all have their rotational axes made inactive, they will not be able to rotate, and so a piece of the chain will appear stiff. Or if only one axis is made active as a sliding joint, the component can separate in space from the chain.

When you are using an object with a path constraint in an IK chain you might want the path to appear as if it is part of the IK chain. You achieve this effect by linking the object using the path constraint and the path to the same parent. The path object should have no children, and other objects in the IK chain should be linked to the object using the path constraint.

In the figure, the bead uses a path constraint to hold it to the ring. The IK chain from parent to child is Post->Cap->Bead->Handle. The ring is a child of the Cap but is not part of the IK chain.

**Copying and Pasting Joint Parameters**

You can copy and paste at the bottom of the Object Parameters rollout in the Hierarchy panel to copy and paste a complete set of joint parameters from one object to another.

There are separate copy and paste functions for sliding joints and rotational joints. Each joint type saves copied parameters in separate clipboards.

Tip: Choose one of the Mirror Paste options if you want to mirror the joint parameter settings as you
paste them. This is very useful when pasting from one side of an object to another, such as left arm joints to a right arm.

You can also copy joint settings from a non-IK controller to an IK controller, but you can’t copy from an IK controller to a non-IK controller.

**Activating Joint Axes**

You set whether an object can move or rotate about a given axis by using the Active check box in the joint rollouts. Joints have a maximum of six possible axes: three for rotation and three for position. You constrain the motion of a joint by setting which axes are active.

- A joint with all axes active can move and rotate freely, independent of its parent.
- A joint with all axes inactive is locked to its parent and cannot move independently.
- The setting of IK joint axes overrides Inherit and Lock settings on the Link Info rollout.

**Understanding Joint Axis Orientation**

IK joint axes for an object are defined by the Local axes of the object’s parent. That means if you activate the X axis of an object’s rotational joint parameters, the object rotates about its parent’s X axis, not its own X axis.

You might have a problem when you set joint parameters for an object whose local coordinate system is oriented 90 degrees from its parent’s coordinate system. In such a case, the rotation angle about one axis becomes indeterminate. The result is that one axis will often cause rotation about one of the other two axes.

The following techniques will make setting joint parameters easier and more successful:

- Assemble IK hierarchies with objects aligned along the World axes.
- Consider using the Adjust Pivot (page 2–488) functions to align your object pivots with either the World axes or the root object of the hierarchy.
- Set the transform managers to Parent coordinate system and Use Pivot Point Center, while setting joint parameters. This helps you see the orientation of the joint axes by displaying the parent axis icon at the selected object’s pivot point.
- When activating joint axes, drag the From spinner up and down. This causes the object to move or rotate about the active axis and is a quick check that you chose the right axis.

**Activating Rotational Joints**

1. Rotational links

When you turn on Active for one of the X, Y, Z axes of a rotational joint, the object can rotate about that axis of its parent’s coordinate system.

Joints that rotate about multiple axes are very common. A ball joint, like your shoulder, is a rotational joint active about all three axes. A pin joint, like your elbow, is a rotational joint active on a single axis.
Chapter 12: Animation

Activating Sliding Joints

1. Sliding axis

When you turn on Active for one of the X, Y, Z axes of a sliding joint the object can move along that axis of its parent’s coordinate system.

Most sliding joints are active only along a single axis. A telescope is an example of a sliding joint active on a single axis. You rarely see a sliding joint active along all three axes.

If a sliding joint is active along all three axes, it moves independently from its parent. It’s almost as if there is no joint connection at all.

Tip: Use the HD IK Solver when you need to use sliding joints with IK.

Path and Surface Joints

When you turn on Active for Path or Surface joints you are setting whether the object can move along the assigned path or surface.

A house key on a ring is an example of an active path joint.

See Path Constraint (page 2–398).

Limiting Joint Action

Most joints are limited in their range of motion along an active axis. For example: a hinge might open only to 120 degrees; a piston slides only within the length of its cylinder. To limit the range of motion allowed on an active axis, you turn on Limited and set values for the From and To fields on the joint rollouts.

You can also view joint limits in the viewport by pressing and holding the mouse button on the From or To label of a limit field. The object will move or rotate to the limit value until you release the mouse button.

Limiting Rotational Joints

Limits for a rotational joint define how far the object can rotate about its parent’s axes. The values in the From and To fields represent the rotation angle about the active axis measured from 0 degrees on the parent object.

For example, an elbow joint rotates the forearm with respect to the upper arm. In the figure the limits on X axis rotation are from 0 to 135 degrees. The Y, Z axes are inactive because an elbow joint rotates about a single axis.

Limiting Sliding Joints

Limits for a sliding joint define how far a joint can move along its parent’s axes. The values in the From and To fields represent a distance for movement along the active axis measured from
the pivot point of the parent to the pivot point of the selected object.

For example, a sliding joint on a piston moves the piston in and out of the cylinder. In the figure, the limits on Z axis movement are from 10 to 90. This prevents the piston from hitting the bottom or moving past the end of the cylinder.

**Limiting Path and Surface Joints**

Limits for path and surface joints define how far along the path or surface an object can move. The values in the From and To fields represent a percentage of the total distance measured along the path or surface.

For example, a path joint for a house key moves the key along a key ring. Setting the limits on the path joint at 5% to 95% prevents the key from traveling along the ring where the fob is attached.

*Sliding and Rotational Joints (HI Solver) (page 2–459)*

**Hierarchy Panel Commands**

Once you have set up a hierarchy using the Select and Link command (page 2–422) or a system such as Bones (page 1–404), you can manage it using the Hierarchy panel. This command panel has three tabs:

- **Pivot** (page 2–487)
- **IK** (page 2–491)
- **Link Info** (page 2–499)

You use the Pivot tab to adjust the pivot points of objects in the hierarchy. You use the IK tab to manage the behavior of inverse kinematics (IK). You use the Link Info tab to apply locks or inheritance to movement within the hierarchy.

*Animating with Applied IK (page 2–481)*

*History-Dependent (HD) IK Solver (page 2–461)*

*History-Independent (HI) IK Solver (page 2–446)*

*IK Limb Solver (page 2–472)*

*Spline IK (page 2–473)*

---

**Pivot**

Make a selection in the viewport. > Hierarchy panel > Pivot button

- **Adjust Pivot**
- **Adjust Transform**

All objects have a pivot point. You can think of the pivot point as representing an object’s local center and local coordinate system. The pivot point of an object is used for the following:

- Functions as the center for rotation and scaling when you select the Pivot Point transform center.
- Sets the default location of a modifier center.
- Defines the transform relationship for the object’s linked children.
• Defines the joint location for inverse kinematics (IK) (page 2–435).

You can adjust the position and orientation of an object’s pivot point at any time using the buttons in the Adjust Pivot rollout in the Hierarchy panel. Adjusting an object’s pivot has no effect on any children linked to that object.

Note: You cannot animate the functions under the Adjust Pivot rollout. Adjusting an object’s pivot on any frame changes it for the entire animation. Use caution when adjusting the pivot of an animated object. Adjusting the pivot on one frame might produce unexpected results in another part of the animation. You should adjust the pivot point to the location you want, before you start to animate, if possible.

Tip: Use the Link constraint (page 2–403) to simulate the effect of an animated pivot.

The Pivot panel has two rollouts:
Adjust Pivot Rollout (page 2–488)
Adjust Transform Rollout (page 2–489)

### Adjust Pivot Rollout

Make a selection in the viewport. > Hierarchy panel > Pivot button > Adjust Pivot rollout

You can adjust the position and orientation of an object’s pivot point (page 3–995) at any time using the buttons in the Adjust Pivot rollout. Adjusting an object’s pivot has no effect on any children linked to that object.

You cannot animate the functions under the Adjust Pivot rollout. Adjusting an object’s pivot on any frame changes it for the entire animation.

Procedure

To reposition an object’s pivot point:

1. Select an object and then turn on Adjust Pivot rollout > Affect Pivot Only.
2. Move or rotate the pivot.

You can also use Align (page 1–462), Normal Align (page 1–465), and Align to View (page 1–468) on the toolbar to align the pivot.

See Adjust Transform Rollout (page 2–489) for related information.

### Interface

**Move/Rotate/Scale group**

Each of the buttons in the Move/Rotate/Scale group box highlights when active. This determines which part of the object is affected by the three buttons in the Alignment area, as well as the Transform and Align commands on the Main toolbar.
Affect Pivot Only—Affects only the pivot point of the selected objects.

Note: A Scale transform has no effect on the pivot.

Affect Object Only—Affects only the selected objects (and not the pivot point).

Affect Hierarchy Only—Affects only the Rotation and Scale tools. It applies the rotation or scale to the hierarchy by rotating or scaling the position of the pivot point without rotating or scaling the pivot point itself.

Note: You can use this on hierarchies of 3ds Max objects, but don’t use it on Bones systems. To reposition, rotate or change the size of bones in a chain, see Bones (page 1–404).

Note: It’s important to remember that the Align, Normal Align, and Align to View functions are all affected by the state of Affect Pivot Only, Affect Object Only, and Affect Hierarchy Only. Snap mode allows you to snap the pivot to its own object, or to any other object in the scene.

Alignment group

The effect of these buttons depends on whether you chose Affect Pivot Only or Affect Object Only. They don’t apply to Affect Hierarchy Only.

If you chose Affect Pivot Only, the buttons work as follows:

Center to Object—Moves the pivot to the center of its object.

Align to Object—Rotates the pivot to align with the object’s transformation matrix axes.

Align to World—Rotates the pivot to align with the world coordinate axes.

If you chose Affect Object Only, the buttons work as follows:

Center to Pivot—Moves the center of the object to its pivot location.

Align to Pivot—Rotates the object to align its transformation matrix axes with the pivot.

Align to World—Rotates the object to align its transformation matrix axes with the world coordinate axes.

Pivot group

Reset Pivot—Resets the pivot point to the position and orientation it held when the object was first created. This is not affected by the state of the Affect Pivot Only and Affect Object Only buttons.

Adjust Transform Rollout

You can transform an object and its pivot without affecting its children using the buttons in Adjust Transform rollout. Adjusting an object’s transforms has no effect on any children linked to that object.
**Procedure**

**To scale a parent without scaling the children:**
1. Select the parent object in a hierarchy.
2. On the Hierarchy panel click the Pivot button if it’s not already on, then on the Adjust Transform rollout, click Don’t Affect Children.
3. Scale the parent object.
   The children will remain unaffected.

Tip: Never use non-uniform scale at the object level for objects in a hierarchical chain. Always go to the sub-object level when you do a non-uniform scale on hierarchically linked objects.

**To reinitialize the scale of an object:**
1. Select an object.
2. In the Adjust Transform rollout > Reset group, click Scale.
   The XYZ values are re-initialized to 100%. This operation will prevent Non Uniform Scale inheritance if a child object is linked to this object.

**Interface**

![Interface diagram]

**Move/Rotate/Scale group**

**Don’t Affect Children**—Limits transforms to the selected object and its axis, not to its children.

This is very useful when working with bones and other hierarchies. If you need to make a particular bone or object longer or shorter, select the object and then turn on Don’t Affect Children. You can readjust it and any parent objects in the hierarchy will stretch or shrink to compensate to the new dimension of the selected bone.

**Reset group**

**Transform**— Resets the orientation of an objects local axis coordinates to align with the world coordinate system, regardless of the current orientation of the object.

This does not affect descendants.

When applied to closed groups, it aligns the dummy node of the parent, but keeps the children in the same place. It reorients and resizes the dummy node to correctly bind the children of the group.

**Scale**— Resets the scale values in the transformation matrix to reflect the new scale of the object. There is no visual change in the object.

You can use the Scale to correct Non Uniform Scale inheritance problems. If Non Uniform Scale is inherited by a child object in a hierarchy, it can result in an undesirable deformation in the child object. To correct for this, use Reset: Scale in the Adjust Transform rollout on an object before linking.

You can view the scale values of the transformation matrix of a selected object. On the toolbar, turn on Scale, then right-click any of the three toolbar Transform buttons (Move, Rotate, or Scale).

There is also a Reset XForm utility (page 1–438) to do the same tasks.

**See also**

Adjust Pivot Rollout (page 2–488)
IK

Make a selection. > Hierarchy panel > IK button

The IK rollouts contain controls for interactive IK and the HD IK solver.

The rollouts for interactive IK are:

- Inverse Kinematics Rollout (page 2–497)
- Auto Termination Rollout (Interactive IK) (page 2–499)

The rollouts for applied IK are:

- Inverse Kinematics Rollout (page 2–497)
- Object Parameters Rollout (HD Solver) (page 2–491)

The rollouts for the HD IK solver are:

- Inverse Kinematics Rollout (page 2–497)
- Object Parameters Rollout (HD Solver) (page 2–491)
- Sliding and Rotational Joints Rollouts (HD Solver) (page 2–496)

Note: The rollouts for the HI IK and IK Limb solvers are not available while IK is chosen in the Hierarchy panel. Most controls for these solvers are found on the Motion panel.

HD IK Solver Rollouts

Object Parameters Rollout (HD Solver)

Make a selection. > Hierarchy panel > IK > Object Parameters rollout

The Object Parameters rollout lets you set IK parameters for an entire hierarchical chain. This topic covers the Terminator check box; other parameters on the Object Parameters rollout are covered in the following topics:

- Position/Orientation/Bind to Follow Object (HD Solver) (page 2–492)
- Precedence (HD Solver) (page 2–494)
- Copying, Pasting, and Mirroring Joint Parameters (HD Solver) (page 2–495)
- Sliding and Rotational Joints Rollouts (HD Solver) (page 2–496)

Procedure

To create a terminator in any hierarchy or HD IK chain:

1. Select an object in any hierarchy or HD IK chain that you want to be the terminator.
2. In the Object Parameters rollout, turn on Terminator.

The terminated objects will not move when you use Interactive, Applied, or HD IK animation.

Interface

Terminator—Sets the base of an IK chain by defining one or more selected objects as terminators.
Turn on Terminator to stop calculation of the kinematic chain before it reaches the root object of the hierarchy. A terminator object stops calculation at the terminator’s child object; the terminator itself is not affected by the IK solution. This gives you very precise control over the behavior of the kinematic chain.

### Position/Orientation/Bind to Follow Object (HD Solver)

Turn on Terminator to stop calculation of the kinematic chain before it reaches the root object of the hierarchy. A terminator object stops calculation at the terminator’s child object; the terminator itself is not affected by the IK solution. This gives you very precise control over the behavior of the kinematic chain.

3. Select one or both of the Bind boxes.
   - Turn on Bind Position to cause the object to attempt to maintain its current location.
   - Turn on Bind Orientation to cause the object to attempt to maintain its current orientation.

**To bind an object to a follow object:**

1. Turn on Bind and select the object in a kinematic chain to be bound.
   Moving your mouse over an acceptable target will change the cursor to a push-pin icon.
2. Drag to the follow object and release.
3. Turn on Bind Orientation if you want the bound object to match the rotation of the follow object. Bind Position is automatically selected.
   Turn off an axis (Axis: XYZ). The specified axis is no longer influenced by the follow object or the New IK Position end effector.
   Use Weight to set the relative influence of multiple follow objects or end effectors, and thus their priority in solving the IK solution. The higher the relative Weight value, the higher the priority.

   **Note:** As you drag, a dotted line is drawn from the pivot point of the selected object to the cursor. When the cursor is over a valid follow object, it changes to a push-pin cursor. Release to set the follow object. The name of the follow object will appear in the text area.

**To unbind an object:**

- Select the object to unbind, and then click Unbind.

   In the text area, the name of the follow object is replaced with the word "None."
**Interface**

**Position group**

<table>
<thead>
<tr>
<th>- Object Parameters</th>
</tr>
</thead>
<tbody>
<tr>
<td>Terminator</td>
</tr>
</tbody>
</table>

**Position:**

- Bind Position
- Axis: X Y Z
- Weight: 1.0

**Bind Position**—Binds the selected object in the IK chain to the world (attempts to maintain its location), or to a follow object, if one has been assigned. If a follow object has been assigned, then the translation of the follow object affects the IK solution.

Note: This check box has no effect on the HD IK Solver Position end effectors, which are always bound to their assigned joints.

**Orientation group**

<table>
<thead>
<tr>
<th>- Orientation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bind Orientation</td>
</tr>
<tr>
<td>Axis: X Y Z</td>
</tr>
<tr>
<td>Weight: 1.0</td>
</tr>
</tbody>
</table>

**Bind Orientation**—Binds the selected object in the hierarchy to the world (attempts to maintain its orientation), or to a follow object, if one has been assigned. If a follow object has been assigned, then the rotation of the follow object affects the IK solution.

Note: This check box has no effect on the HD IK Solver Rotation end effectors, which are always bound to their assigned joints.

**R**—Establishes a relative position offset or rotation offset between follow object and end effector.

This button has no effect on the HD IK Solver Position end effectors. They are created on top of the joint to which they’re assigned, and are automatically absolute.

If you move the joint away from the end effector, and want to reset the end effector to an absolute position, you can delete and then recreate the end effector.

**Axis X/Y/Z**—If one of the axes is turned off, the specified axis is no longer influenced by the follow object or the HD IK Solver Position end effector.

For example, if you turn off the X axis in the Position group, movement of the follow object (or end effector) along the X axis has no effect on the IK solution, but movement along the Y or Z axis has.

Note: These do not constrain the movement of the follow object or end effector.

**Weight**—Sets the influence of the follow object (or end effector) on its assigned object, and on the rest of the chain. A setting of 0 turns off the binding. Using this value you can set the relative influence of multiple follow objects or end effectors and their priority in solving the IK solution. The higher the relative Weight value, the higher the priority.

The Weight settings are relative; there’s no point in using them if there’s only one follow object or end effector in your IK hierarchy.

However, if you have a single HD IK chain with both Position and Rotation end effectors on a single joint, you can give them different weights to give priority to either the position or rotation solution.

You can adjust the Weight for multiple joints. Select two or more objects in the hierarchy, and the Weight value represents the commonality of the selection set.

Note: Differences in the Weight values only have an effect when there is no solution that satisfies two or more opposing end effectors in the chain. In
this case, the end effector with the greatest weight "wins."

### Bind To Follow Object group

<table>
<thead>
<tr>
<th>Icon</th>
<th>Label</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image" alt="Icon" /></td>
<td>Bind To Follow Object: None</td>
<td>Controls to bind and unbind an object in an inverse kinematic chain to a follow object.</td>
</tr>
<tr>
<td><img src="image" alt="Icon" /></td>
<td>Bind</td>
<td>Binds an object in an inverse kinematic chain to a follow object.</td>
</tr>
<tr>
<td><img src="image" alt="Icon" /></td>
<td>Unbind</td>
<td>Unbinds the selected object in a HD IK chain from its follow object.</td>
</tr>
</tbody>
</table>

### (Label)—Displays the name of the selected follow object. Displays the word "None" if no follow object is set.

### Bind—Binds an object in an inverse kinematic chain to a follow object.

### Unbind—Unbinds the selected object in a HD IK chain from its follow object.

### Precedence (HD Solver)

You can use the three joint precedence controls to alter how the IK Solution is calculated.

The default joint precedence is 0. This is suitable for many IK solutions. It assumes that joints closest to where a force is applied (the end effector) will move more than joints farther from the force.

- **Child->Parent**—values are calculated by assuming the root of the entire hierarchy has a precedence value of 0 and each child has a value equal to 10 times its depth from the root. In a four-object hierarchy starting with the root, the values would be 0, -10, -20, and -30.
- **Parent->Child**—values are calculated by assuming the root of the entire hierarchy has a precedence value of 0 and each child has a value equal to 10 times its depth from the root. In a four-object hierarchy starting with the root, the values would be 0, -10, -20, and -30.
- **Default joint precedence occurs whenever all joints in the kinematic chain have the same precedence value. Assigning a value of 100 to all objects in the kinematic chain is exactly the same as assigning a value of 0.**
- **An IK chain of three objects with precedence values of 0, 30, and 200 would have the same solution if the precedence were changed to be 1, 2, and 3.**

### Procedures

#### To assign a precedence value to an object manually:
1. Select an object in an HD IK Chain.
2. Open the Object Parameters rollout in the Hierarchy panel.
3. Enter a value in the Precedence field.

#### To assign Child->Parent precedence to all objects in a kinematic chain:
1. Select all objects in an HD IK chain.
2. Open the Object Parameters rollout in the Hierarchy panel.
3. Click Child->Parent.

#### To assign Parent->Child precedence to all objects in a kinematic chain:
1. Select all objects in the kinematic chain.
2. Open the Object Parameters rollout in the Hierarchy panel.
3. Click Parent->Child.

#### To reset the default joint precedence:
1. Select all objects in the kinematic chain.
2. Open the Object Parameters rollout in the Hierarchy panel.
3. Set the value in the Precedence field to 0.
Interface

Three controls set precedence:

**Precedence**—Manually assigns precedence values to any object in the IK chain. High precedence values are calculated before low precedence values. Precedence values that are equal are calculated in Child>Parent order.

**Child>Parent**—Automatically sets joint precedence to decrease in value from child to parent. Causes joints closest to where a force is applied (the end effector) to move more than joints farther away from the force.

You almost always assign Child>Parent precedence to an entire kinematic chain.

Child>Parent behaves like the default precedence settings but is more flexible if you want to go back and manually change the settings.

**Parent>Child**—Automatically sets joint precedence to decrease in value from parent to child. Causes joints closest to where a force is applied (the end effector) to move less than joints farther away from the force.

You almost always assign Child>Parent precedence to an entire kinematic chain.

**Copying, Pasting, and Mirroring Joint Parameters (HD Solver)**

Make a selection. > Hierarchy panel > IK > Object Parameters rollout > Copying, Pasting, and Mirroring joint parameters

Use the Copy and Paste buttons in the Object Parameters rollout to copy and paste the joint settings between IK controllers. You can also copy joint settings from a non-IK controller to an IK controller, but you can’t copy from an IK controller to a non-IK controller. With an HD IK solver hierarchy, you can paste to a multiple selection of joints.

Use Mirror Paste to mirror the IK joint settings about the X, Y, or Z axis during a Paste operation. It consists of four buttons: one each for the X, Y, and Z axes, and a None option that prevents mirroring altogether.

You can also mirror the IK joints using the Mirror tool on the main toolbar.

**See also**

*Sliding and Rotational Joints (page 2–496)*

**Procedure**

**To copy and paste joint parameters:**

1. Select an object in an inverse kinematic chain.
2. Set sliding or rotational joint parameters.
3. Click Copy in either the Sliding Joints or Rotational Joints group on the Object Parameters rollout.
4. Select a different object in the inverse kinematic chain.
5. Select an axis to mirror in the Mirror Paste group.
6. Click paste in either the Sliding Joints or Rotational Joints group on the Object Parameters rollout.

Both Sliding Joints and Rotational Joints maintain separate clipboards. The copied joint parameters are saved in the clipboard until you replace them with new copied parameters.
Interface

Sliding Joints group
Use these buttons to copy sliding joint parameters from one object to another. These buttons are not available for Path joints.

Rotational Joints group
Use these buttons for copying rotational joint parameters from one object to another.

Mirror Paste group
Use to mirror the IK joint settings about the X, Y, or Z axis during a Paste operation.

 Procedures

To activate or deactivate an axis:
1. Select an object.
2. On the Hierarchy panel, click IK.
3. Expand the rollout for a joint type.
4. Turn on Active for any available axis.
   - When on, the axis is active and the object can move or rotate about that axis.
   - When off, the axis is inactive and the object cannot move or rotate about that axis.

To limit a joint:
1. Select an object.
2. Click IK in the Hierarchy panel.
3. Turn on Limited for any active axis. If an axis is inactive the limits settings are ignored.
   - When on, the axis is limited and the object can move or rotate within the range set by the From and To fields.
   - When off, the axis is not limited and the object moves or rotates freely about that axis. If you turn on Limited, specify limit values in the From and To fields. When setting limits, the object transforms to the position or rotation defined by the From or To field. When you exit the field or release the spinner, the object returns to its original position. You can also view joint limits in the viewport by pressing and holding the mouse button on the From or To label of a limit field. The object will move or rotate to the limit value until you release the mouse button.
Interface

Sliding/Rotational Joints rollouts

The Sliding Joints rollout and Rotational Joints rollout contain similar controls for position and rotation, respectively. Also, each rollout contains identical group boxes for control of the X, Y, and Z axes.

X/Y/Z Axis groups

Active—Activates an axis (X/Y/Z). Allows the selected object to slide on or rotate about the activated axis.

Limited—Limits the range of motion or rotation allowed on an active axis. Use in conjunction with the From and To spinners. Most joints are limited in their range of motion along an active axis. For example, a piston slides only within the length of its cylinder.

Ease—Causes a joint to resist motion as it approaches its From and To limits. Simulates an organic joint, or worn mechanical joint, moving or rotating freely in the middle of its range of motion but moving less freely at the extremes of its range.

From and To Spinners—Determine for position and rotation limits. Use in conjunction with the Limited function.

Spring Back—Activates Spring Back. Each joint has a rest position. As the joint moves further from the rest position, an increasingly larger force pulls the joint back to its rest position, like a spring.

Spring Back (spinner)—Sets the rest position for the joint. For rotational joints, this is the orientation of the joint in degrees; for sliding joints, it's the position in units. Adjusting this is similar to adjusting the From/To spinners. You see the orientation/position while performing the adjustment, but when you release the spinner the object returns to its previous state.

If you’re using the HD Solver, you must turn on Show Initial State (Motion panel > IK Controller Parameters rollout) to see the effect on the geometry during the adjustment.

Spring Tension—Sets the strength of the "spring." Higher values cause the spring to pull harder as the joint moves further from its rest position. A setting of 0 turns off the spring; very high settings can turn the joint into a limit because you can reach the point where the spring is too strong to allow the joint to move past a certain point.

Damping—Applies resistance over a joint’s full range of motion or rotation. Simulates the natural effect of joint friction or inertia. As a joint corrodes, dries out, or is put under a heavy load, it resists motion along its active axes.

Interactive and Applied IK Rollouts

Inverse Kinematics Rollout

Make a selection. > Hierarchy panel > IK > Inverse Kinematics rollout

The Inverse Kinematics rollout displays different controls based on IK Solvers applied to the selected
Chapter 12: Animation

hierarchy. IK Solvers are applied to the hierarchies using the Animation menu.

When an HD IK Solver is applied to an IK chain the Inverse Kinematics rollout displays the controls described below.

The Inverse Kinematics rollout provides controls for interactive and applied IK, as well as the controls for the HD Solver (history dependent). Use Apply IK to calculate an IK solution and generate Transform keys (move, rotate) for all objects in an IK chain (the IK chain must include a follow object). By default, keys are created at every frame.

- Applied IK requires that one or more parts of your IK structure be bound to animated follow objects. Once bound, you can select any object in your kinematic chain and click the Apply IK button.
- The Apply IK method of animation works best when you want objects in the kinematic chain to match the motions of other objects exactly. An example of this would be a mechanical connection that should always appear to be attached to the follow object.

Procedures

To use interactive IK:
1. Build a hierarchy of objects.
   If you want to use Bones, be sure Assign to Children is not active when you create the Bones.
2. Select the end of the chain.
3. Go to the Hierarchy panel > IK button.
4. Scroll up to the Inverse Kinematics Rollout
5. Click Interactive IK.
6. Advance the time slider and move the end of the chain.
7. Turn off Interactive IK when you want to do forward kinematics.

To use applied IK:
1. Add an HD Solver to your hierarchy.
2. Bind objects in your IK structure to follow objects.
3. Animate the follow objects.
4. Select any object in the IK structure.
5. Click IK in the Hierarchy panel and expand the Inverse Kinematics rollout.
6. Click Apply IK.
   Tip: Be sure your Start Frame and End frames match the length of your animation.

Interface

Interactive IK—Allows for IK manipulation of hierarchies without applying an IK Solver or using a follow object.

Apply IK—Calculates the IK solution for each frame of the animation and creates transform keys for every object in the IK chain. A bar graph appears on the prompt line to indicate progress of the calculations.

Apply Only To Keys—Solves the IK solution for keyframes that already exist for one of the end effectors.
**Update Viewports**—Views the progress of Apply IK frame by frame in the viewports.

**Clear Keys**—Removes all move and rotate keys from the selected IK chain before applying IK.

**Start/End**—Sets the range of frames to calculate the applied IK solution. The default settings for Apply IK calculates the IK solution for every frame of the active time segment.

---

**Auto Termination Rollout (Interactive IK)**

Make a selection. > Hierarchy panel > IK button > Auto Termination rollout

The Auto Termination controls temporarily assign terminators a specific number of links up the hierarchical chain from the selected object. This only works with Interactive IK; it does not work with applied IK or with IK solvers.

**Procedure**

**To use auto termination:**

1. In the Auto Termination rollout, turn on Auto Termination.
2. Enter a value in the # of Links Up field.
   
   Turn on the IK button on the toolbar.
3. Select any object in an IK chain to move or rotate.

**Interface**

**Interactive IK Auto Termination**—Turns on the auto termination feature.

---

**# of Links Up**—Specifies how far up the chain the termination is applied.

For example, if you set this to 5, when you move any object in the hierarchy, the object that’s five links up the chain from the object you’re adjusting acts as a terminator. If you select a different object in the hierarchy, termination is switched to whichever object is five links up the chain from the newly selected object.

A setting of 1 simply locks the hierarchy, since it terminates the joint just beyond the currently selected object.

---

**Link Info**

Make a selection. > Hierarchy panel > Link Info button

This part of the Hierarchy panel contains two rollouts. The Locks rollout has controls to restrict the movement of objects in a particular axis. The Inherit rollout has controls to limit the transforms that a child inherits from its parent object.

**Interface**

<table>
<thead>
<tr>
<th>Pivot</th>
<th>IK</th>
<th>Link Info</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>Locks</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Inherit</td>
</tr>
</tbody>
</table>

The Link Info panel has two rollouts:

**Locks rollout (page 2–500):** Locks an object’s ability to Move, Rotate, or Scale about any of its local axes.

**Inherit rollout (page 2–500):** Limits what transforms a child inherits.
Locks Rollout

Make a selection. > Hierarchy panel > Link Info button > Locks rollout

The Locks rollout contains controls that prevent transforms along particular axes.

See also

Inherit Rollout (page 2–500)

Procedure

To lock all move transforms:
1. Select an object in the viewports.
2. In the Locks rollout, turn on Move group > X, Y, and Z.

Only rotate and scale transforms will work.
The object does not need to be part of a hierarchy.

Interface

<table>
<thead>
<tr>
<th>Move:</th>
<th>Inherit</th>
</tr>
</thead>
<tbody>
<tr>
<td>✓ X ✓ Y ✓ Z</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Rotate:</th>
<th>Inherit</th>
</tr>
</thead>
<tbody>
<tr>
<td>✓ X ✓ Y ✓ Z</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Scale:</th>
<th>Inherit</th>
</tr>
</thead>
<tbody>
<tr>
<td>✓ X ✓ Y ✓ Z</td>
<td></td>
</tr>
</tbody>
</table>

X, Y, Z—Turn on any axis in the Move, Rotate, or Scale group box to lock the axis. For example, if Rotate > X and Y are turned on, you’ll be able to rotate the object only around the Z axis. All locks are relative to an object’s local coordinate system.

Inherit Rollout

Make a selection. > Hierarchy panel > Link Info button > Inherit rollout

The Inherit rollout constrains the links between a selected object and its parent for any axis of position, rotation, or scale.

See also

Locks Rollout (page 2–500)

Procedure

To prevent inheritance of X rotation in a hierarchy:
1. Select an object, then turn off X in the Rotate group on the Inherit rollout.

Interface

<table>
<thead>
<tr>
<th>Move:</th>
<th>Inherit</th>
</tr>
</thead>
<tbody>
<tr>
<td>✓ X ✓ Y ✓ Z</td>
<td></td>
</tr>
</tbody>
</table>

X, Y, Z—Turn off any axis in the Move, Rotate, or Scale group boxes to prevent inheritance.

When you turn on an axis, transform information passes from the parent to the child for that axis.
When you turn off an axis, transform information on that axis is ignored by the child.
Track View

Main toolbar > Curve Editor (Open)

Graph Editors menu > New Track View

Graph Editors menu > Track View - Curve Editor

Graph Editors menu > Track View - Dope Sheet

Graph Editors menu > Saved Track View > Choose a saved Track View.

Right-click active viewport. > Transform quadrant > Curve Editor or Dope Sheet

Viewport right-click menu > Views > Track > Choose New or a saved Track View.

With Track View, you can view and edit all the keys that you create. You can also assign animation controllers to interpolate or control all the keys and parameters for the objects in your scene.

Track View uses two different modes, Curve Editor and Dope Sheet. Curve Editor mode lets you display the animation as function curves. Dope Sheet mode displays the animation as a spreadsheet of keys and ranges. Keys are color-coded for easy identification. Some of the functions in Track View, such as moving and deleting keys, are also available on the track bar near the time slider, which can be expanded to show curves as well. You can dock the Curve Editor and Dope Sheet windows beneath the viewports at the bottom of the interface, or use them as floating windows. Track View layouts can be named and stored in the Track View buffer and reused. Track View layouts are stored with the MAX file.

Typical Uses for Track View

Track View can perform a variety of scene management and animation control tasks. Use Track View to:

- Display a list of objects in your scene and their parameters.
- Change key values.
- Change key timing.
- Change controller ranges (see procedure).
- Change interpolation between keys.
- Edit ranges of multiple keys.
- Edit blocks of time.
- Add sound to your scene.
- Create and manage notes about the scene.
- Change the behavior of the animation outside the range of keys.
- Change controllers for animated parameters
- Select objects, vertices, and hierarchies.
- Navigate the modifier stack in the Modify panel by clicking the modifier items in the Track View Hierarchy.

Note: Tracks are created for animated vertices in Track View. A Bezier Point3 controller is the default vertex interpolation controller.
Procedures

To change the frames in which a controller takes effect:

When you apply a controller or constraint to an object’s motion, the frame range over which controller takes effect is determined by the current active time segment (page 3–904). If you then change the active time segment or the animation length, the duration of the controller’s influence doesn’t change. Sometimes applying a controller (such as Path Constraint) automatically sets keys that you can use to change this range. But others, such as Noise controllers, don’t set keys. In such cases, follow this procedure:

1. Select the object, and then right-click it and choose Curve Editor from the menu.
2. Expand the object hierarchy to find the track or tracks to adjust.
3. From the Modes menu, choose Dope Sheet.
4. On the Dope Sheet, click the Edit Ranges button.
5. Adjust the range duration by dragging its endpoints, or its position in the animation by dragging between endpoints.

For more information, see Dope Sheet (page 2–507).

To select keys in Track View (either mode), do any of the following:

- Click the key to select an individual key.
- Drag a selection rectangle around keys to select multiple keys.
- Hold down the Ctrl key and click to create discontinuous multiple key selections.

Note: If you are in Dope Sheet – Edit Ranges mode, you can use Select Time to select multiple keys.

To delete keys in Track View (either mode):

1. Select keys on the curve, or on the dope sheet.
2. Press the Delete key on the keyboard to delete the selected keys.

To force Track View to always display on a second monitor:

If you are running a dual-monitor setup, you can force Track View to display on the right-hand monitor by editing a script.

1. Right-click the Curve Editor (Open) icon in the main toolbar, and then choose Edit Macro Script.

The MAXScript script that opens the Track View – Function Curve Editor appears.

2. Locate the line that reads:

   if (trackviews.open "Track View - Curve Editor" layoutName:"Function Curve Layout") == true then

3. Replace that line with this one:

   max_window = getMaxWindowSize() --get Desktop size if (trackviews.open "Track View - Curve Editor" layoutName:"Function Curve Layout" pos:[max_window.x/2,0] height:max_window.y width:(max_window.x/2) ) == true then

4. Save the script and restart 3ds Max.

This should open the Track View in a new session over the right half of the desktop. Assuming that a dual-monitor setup reports twice the width, this will force the Track View on the second monitor. On a single monitor, it opens it over the right half of the monitor. Of course, you could enter your own numbers like pos:[1024,0] height:768 width:1024 in case you are running two monitors at 1024x768.
To open Track View in a viewport:
- Right-click a viewport label, and then from the menu that opens choose Views > Track > New, or click the name of a saved Track View.

Working with Track View

Track View is the tool that you use to see a data-driven view of your scene and animation.

The standard views, such as Top, Front, User, and Camera, are geometry-driven views. These views display the surfaces of your objects and show them changing over time.

Track View displays the values and timing that produce the geometry and motion you see in standard views. Using Track View, you have very precise control over every aspect of your scene.

Track View has two modes: Curve Editor and Dope Sheet. The Curve Editor displays your animation as keys on function curves; editing the tangency of the keys allows control of the in-betweens. Dope Sheet displays your animation as keys and ranges on a box grid and allows you to adjust the timing of your motions.

Track View keys and curves can also be displayed in the track bar. The same Key properties dialogs available on Track View can also be found on the Motion panel as well.

For details about using Track View and editing animation, see the following:
- Track View Edit Window (page 2–504)
- Track View Menu Bar (page 2–521)
- Curve Editor Toolbars (page 2–535)
- Dope Sheet (page 2–507)
- Dope Sheet Toolbars (page 2–538)

Understanding Track View Concepts

The left side of Track View, called the Controller Window, presents a Hierarchy list of everything in your scene. Every object and environment effect appears in the list, along with its associated animatable parameters. Choose items from this list to apply changes to the animation values. Expand or collapse the list using manual navigation, or allow the Auto expand to determine the display in this window.
The right side of Track View, called the Key window, charts the changes applied to parameters over time. Any change you make to one of these parameters when the Auto Key button is on, appears as a key in the right side of Track View. Select keys to apply changes to one or more specific keys.

This section covers some of the editing functions you can use with Track View:

- Copying and Pasting Items (page 2–575)
- Copying and Pasting Objects (page 2–576)
- Making Instance and Reference Controllers and Objects Unique (page 2–577)

### Track View Workspace

The Track View Key window displays function curves and keys when in Curve Editor mode. When in Dope Sheet mode, the tracks can be displayed as keys or ranges. You select and change animation values and timing in these windows. The Key window also indicates the active time segment. Time within the active time segment is highlighted with a light gray background. The Track View Key window is sometimes referred to as the Key window.

Components of the Key window include a time slider, a time ruler, and a scale origin slider. The Track View time slider indicates the current frame and is synchronized with the viewport time slider. A time ruler at the bottom of the window can be raised to measure keys against time. A scale origin indicator (a horizontal orange line at 0) can be moved during scale value operations as a reference point for scaling.

### Interface

The two main sections of the Track View workspace consist of the Key window and the Controller window.

### Controller Window

The Controller window displays object names and controller tracks, and determines which curves and tracks are available for display and editing. Hierarchy items in the Controller window can be expanded and rearranged as necessary using the Hierarchy list right-click menu. The navigation tools can also be found in the Track View Options menu. Default behavior is to only show selected object tracks. Use Manual Navigation mode to collapse or expand tracks individually, or press `Alt`+right-click to display an alternate menu to collapse and expand tracks.
Key window

The Key window displays the keys as either curves or tracks. The tracks can be displayed as a box graph of keys or range bars.

Key Creation

Keys are created using a variety of methods. Keys can be created by turning on Auto Key, moving the time slider, and then transforming the object or adjusting its parameters. Keys can also be created by right-clicking the viewport time slider to access the Create Key dialog. Keys can be created directly in Track View using Add Keys. Finally, keys can be created by turning on Set Key mode, moving to a desired frame, posing the object, then clicking Set Key.

Key Display

Keys are displayed as points on the function curves, or as boxes on the Dope Sheet. Keys on the Dope Sheet are color-coded for easy identification. When there are multiple tracks keyed at one frame, the boxes appear with bands of color to indicate the shared key types. Key coloration is also used to show soft selection of keys. Subframe keys (keyframes that fall between frames) are indicated as narrow rectangles within the boxes.

Range Bars

In the Dope Sheet - Edit Ranges mode (when animation keys have been created), range bars display to indicate the range of time the animation occurs. Tools specific to working with ranges (position ranges and recouple ranges) can be found on the Ranges toolbar (off by default).
Right-click the toolbar, choose Show Toolbars, and then select Range-Track View to access these tools.

Keys displayed as range bars (Dope Sheet - Edit Ranges mode)

Function Curves

Function Curves display the values of keys, and the interpolated values between keys, as a curve. These curves express how a parameter varies over time. Only animation tracks can display function curves. You can edit the curves using tangency handles on the keys to change the shape of the curve.

Keys displayed as function curves (Curve Editor)

Multiple curves can be viewed simultaneously by selecting tracks in the Controller window. This is especially useful when using Multiplier or Ease Curves. You can adjust the multiplier or ease curve point tangencies and watch the final result in the controller curve at the same time.

Time Ruler

The time ruler measures time. Markings on the ruler reflect the settings in the Time Configuration dialog. Move the time ruler up to the keys for more accurate key placement.

Time ruler

Track View Time Slider

The current time is indicated by the Track View time slider. This is displayed as a set of blue vertical lines synchronized with the position of the viewport time slider. You can move the Track View time slider by dragging it in the Key window. Moving either time slider updates the animation in the viewports. The blue time slider also serves as a scale origin point when scaling keys in time.

Scale keys using time slider

Scale Values Origin Line

When you choose to scale key values (that is, scaling in space rather than time), a horizontal orange line appears at the 0 value on the vertical graph axis. This orange line is a scale values origin indicator, which you can move vertically to use as a reference point for scaling values.
Horizontal line at the top of the illustration is the moveable scale origin line.

**Curve Editor**

Menu bar > Graph Editors > Curve Editor

Menu bar > Graph Editors > New Track View > Modes > Curve Editor

Main toolbar > Curve Editor (Open)

Right-click the selected object in the viewport. > Curve Editor

The Track View - Curve Editor is a Track View mode that allows you to work with motion expressed as function curves on a graph. It lets you visualize the interpolation of the motion, the object transformations that the software creates between the keyframes. You can easily see and control the motion and animation of the objects in the scene using tangent handles on the keys found on the curves.

The Curve Editor interface consists of a menu bar, a toolbar, a Controller window, and a Key window.

There is also a time ruler, and navigation and status tools at the bottom of the interface.

You can loop or cycle your animation beyond its range by adding Parameter Curve Out-Of-Range Types from the Curve Editor, as well as by adding Multiplier or Ease Curve onto other animated tracks for added control.

Tip: You can also click Show Curves in the track bar to display function curves.

*Curve Editor Toolbars (page 2–535)*

**Dope Sheet**

Menu bar > Graph Editors > Track View - Dope Sheet

Menu bar > Graph Editors > New Track View > Modes > Dope Sheet

Main toolbar > Curve Editor (Open) > Modes menu > Dope Sheet

Right-click the selected object in the viewport > Curve Editor > Modes > Dope Sheet

The Track View - Dope Sheet editor displays keyframes over time on a horizontal graph. This graphical display simplifies the process of adjusting animation timing because you can see all keys at once in a spreadsheet-like format.

Classical animation technique included the use of an exposure sheet, called an “X” sheet or a Dope
Sheet. The Dope Sheet was a vertical chart that served as instructions to the camera operator. Dialogue and camera actions were indicated over a numbered list that represented each shot, which became a single photographed frame of the animated movie. The classical exposure sheet also included instructions for compositing the cel drawings of animated characters over backgrounds. This device serves as inspiration for the Dope Sheet tool in 3ds Max.

The 3ds Max Dope Sheet editor is similar to the classic X sheet. It displays keyframes over time, only using a horizontal graph (rather than vertical). This provides tools for adjusting the timing of your animation. Here, you can see all the keys in a spreadsheet-type interface. You can select any or all of the keys in a scene, scale them, move them, copy and paste them, or otherwise work directly here, rather than in the viewport. You can choose to select the keys for children, or subtree or both, so you can make simple changes that affect many objects and their keys at once.

A common use of Dope Sheet is to stagger the movement of a character’s limbs so they don’t all move simultaneously. If you have a crowd of characters, you could use Dope Sheet to shift movements so they don’t all move in unison.

Dope Sheet Menus and Tools

In the Dope Sheet, you can select any or all of the keys in a scene, scale them, move them, copy and paste them, or otherwise work directly, rather than working with objects in viewports. You can choose to select the keys for children, or subtree or both, so you can make simple changes that affect many objects and their keys at once.

Dope Sheet allows for soft-selection of keys which is very useful when working with motion capture data that has keys on every frame.

Dope Sheet provides tools for working directly with time. You can select, cut, copy, paste, and insert and reverse time using the tools on the Time menu.

Like the Curve Editor (page 2–507), Dope Sheet has both a menu bar and toolbars to provide you quick access to tools.

Dope Sheet menu bar

Unlike Curve Editor, Dope Sheet has two modes: Edit Keys and Edit Ranges. These modes change the display in the Key window.

Edit Keys Mode

When Edit Keys is turned on, the keyframes are displayed as boxes within rectangles on a grid. The keys are color-coded to show what has been keyframed (position is red, scale is yellow, rotation is green, and so on.)

Colored keys

Dope Sheet keys are now displayed as rectangles within boxes so you can easily spot sub-frame keys, keys that fall in between frames. Keys that fill the boxes are on the frame, keys that are small rectangles are sub-frame.
Dope Sheet, just like the Curve Editor, allows you to use soft selection on keys. This is extremely useful when you are dealing with massive quantities of keys, such as in motion-capture data files. Combine this with scaling keys for a means to manipulate motion data.

Modify Subtree and Modify Child Keys

When working in Dope Sheet, you can turn on or off Modify Subtree and Modify Child Keys. These let you automatically move the keys for the children, and/or the tracks for the subtree. If you experience a slowdown while working with Dope Sheet, try turning these off, and moving the keys manually instead. Modify Subtree is on by default in Dope Sheet, but off in Curve Editor.

Time Editing

Dope Sheet offers you a variety of tools for working directly with time. You can select a period of time, which includes all the keys within that period, and then perform different operations on that time segment. You can copy and paste time to loop animations, or reverse time so the animation plays backward. You can insert time to add a space to an animation, or delete time to shorten a motion.

Note: For Dope Sheet procedures, see the individual tools and menu choices within the links below.

Dope Sheet Speed Improvements

In 3ds Max, only tracks displayed in the current field of view are computed, optimizing the responsiveness of the Dope Sheet editor.

Dope Sheet now temporarily retains the key caches so tracks that have already been computed as a result of the parent being computed needn’t be recomputed. The cache is used instead.

The default auto-navigation settings for the Dope Sheet editor now only auto-expand to the node track for the currently selected object. This reduces the number of tracks whose keys need to be displayed and also helps enforce the top-down workflow the Dope Sheet editor is designed for.

Edit Ranges (page 2–573)
Edit Keys (page 2–554)

Time Ruler

Main toolbar > Curve Editor (Open) > Time Ruler (below right-hand pane)
Graph Editors menu > Track View - Curve Editor/Track View - Dope Sheet > Time Ruler (below right-hand pane)

The time ruler at the bottom of the Track View Key window measures time. Markings on the time ruler reflect the settings in the Time Configuration dialog (page 3–725). You can drag the time ruler vertically in the Key window to align it with any track.

Track View Shortcuts

Track View functions for which keyboard shortcuts can be set are listed below. Where there is no default keyboard listed and no button shown in the action list, a short description appears in the right column.

To use Track View keyboard shortcuts, the Keyboard Shortcut Override toggle (page 3–872) must be on.

### Track View Hierarchy

Main toolbar > Curve Editor (Open) > Track View Controller Window

Graph Editors menu > Track View - Curve Editor/Track View - Dope Sheet

The Track View Controller window displays all objects in your scene in a hierarchical fashion. You select objects in the Hierarchy list to:

- Select object and track labels for Track View operations.
- Select object icons to select objects in the scene.
- Select material or map icons when working in the Material Editor.
- Select modifiers in Track View to navigate the modifier stack in the Modify panel.

**See also**

- Hierarchy Right-Click Menu (page 2–516)
- Properties (Track View Hierarchy) (page 2–519)
- Modify Subtree (page 2–528)
- Sound Options Dialog (page 2–520)
Procedures

To select objects in the scene using the Track View Controller window:

1. Do one of the following to select the first object:
   - Click an object’s icon to select a single object.
   - Double-click a parent object’s icon to select an object and its descendants.

2. Do one of the following to select additional objects:
   - Press \[\texttt{Shift}\] and click an object icon to select all objects between the object and the previously selected object.
   - Press \[\texttt{Ctrl}\] and click an object icon to add (or remove) the object to the selection.

When objects are selected in the scene, their icons are also highlighted in Track View.

All objects in your scene are always displayed in Track View. However, selecting object icons in Track View follows the same rules as selecting objects in the scene:

- You can’t select the icon of a hidden object.
- You can’t select the icon of a frozen object.
- If you select the icon of an object that is part of a closed group, the group icon and all the objects in the group are selected.

To select and deselect item labels by clicking:

1. Select the first item by clicking its label.

2. Do one of the following to add or subtract from the selection:
   - Press \[\texttt{Shift}\] and click an item label to select all items between the item and the previously selected item.
   - Press \[\texttt{Ctrl}\] and click an item label to add (or remove) that item to the selection.
   - Press \[\texttt{Alt}\] and click an item label to select all item labels in the column.

Right-clicking an item displays a right-click menu for globally selecting items in the Hierarchy list.

To select items in the Controller window with the right-click menu:

- Right-click an item in the Controller window, then do any of the following:
  - Choose Select All to select all items visible in the Hierarchy list. Collapsed items are not selected. Press \[\texttt{Ctrl}\] and choose Select All to select only visible transform items.
  - Choose Select Invert to reverse the selection pattern.
  - Choose Select None to clear all items from the selection.
  - Choose Selected Children to select the linked descendants of a parent object.

When working with function curves, you can also select a controller icon (instead of the label) to select that function curve for vertex editing.

To select a material or map as the active material in the Material Editor:

1. Open the Material Editor.

2. Open the Medit Materials branch in the Hierarchy list of the Controller window and select a material.

   The selected material becomes the active item in the Material Editor. This is one way to navigate and select a material for editing.

Example: To navigate the modifier stack in the Modify panel:

1. Create a cylinder.

2. In the Modify panel, add a Bend and a Twist modifier to the cylinder.

3. In the Track View controller window, expand the Cylinder branch.

4. Expand the Modified Object branch.
5. Click the icon of the Twist modifier.
   The Twist modifier is displayed on the Modify panel.

6. Click the icon of the Bend modifier in the Hierarchy list.
   The Bend modifier is displayed on the Modify panel.

To highlight all tracks containing animation:
1. Create a box and a sphere.
2. Click Auto Key, go to frame 10 and move the sphere in X.
3. Go to frame 20 and move the sphere in Y.
4. Go to frame 30 and move the sphere in Z.
5. Deselect the sphere by clicking in a blank area of the viewport.
6. Open the track View — Curve Editor and press Ctrl+A.

   Locate in the Track View Controller window the box and sphere objects. Notice that both their icons are highlighted as well as the sphere's XYZ position tracks.

Interface

World—World is the root of the scene hierarchy. This track collects all keys in your scene as a single range for quick global operations.

By default, the World track shows the range of the Sound, Environment, Medit Materials, and Scene Materials branches. Modify Subtree in Edit Ranges mode causes the World track to include the range of all tracks in the Objects branch as well.

Note: The default location of the time ruler covers the World animation track. Move the time ruler to see the World track.

Sound—Allows you to synchronize your animation to a sound file or to a metronome. If you use a sound file, a Wave Form track is displayed in the Hierarchy list, and a waveform is displayed in the Edit window. A sound file plays on your installed sound card. You set the Metronome and the Wave Form parameters in the Sound Options dialog (page 2–520).
**Global Tracks**—Allows you to store controllers for global use. Using expression controllers, for example, you could point to a controller in the Global Tracks from several other tracks. By altering the expression in the Global Tracks, all of the other tracks are changed.

By pasting an instance of a controller in Global Tracks to a number of other tracks, you can change many tracks by altering the controller in Global Tracks.

By default, Global Tracks contains List tracks of the different controller types. To assign a controller, open one of the List tracks, highlight the available track, and then click Assign Controller. Once the controller is assigned, you can point to it from an expression controller assigned to any other track, or you can copy and paste it to any number of matching controller types.

**Video Post**—Allows you to manage animated parameters for Video Post plug-ins.

**Environment**—Contains items that control the background and scene environment effects. Examples include Ambient Light, Background definition, Fogs, and Volumetric Lighting.

**Render Effects**—Contains tracks for the effects added in Rendering menu > Effects. After adding rendering effects, use the tracks here to animate effects parameters such as glow size and color.

**Render Elements**—Shows you what elements you’ve chosen to render separately via the Render Scene dialog > Render Elements rollout.

**Renderer**—Allows you to animate parameters in the renderer. After selecting a type of antialiased in the Render dialog, you can animate various antialiased parameters using these tracks.

**Global Shadow Parameters**—Use these tracks to change or animate shadow parameters for any light that has the Use Global Settings parameter turned on in the Shadow Parameters rollout.

(Select a light, then open the Modify panel > Shadow Parameters rollout to toggle the Use Global Settings parameter).

You can change shadow parameters for multiple lights simultaneously. Tracks include Map Size, Map Range, Map Bias, and Absolute Bias (page 2–1337).

**Scene Materials**—Contains the definitions for all materials in the scene. It is empty until you begin assigning materials to objects. When you select materials in this branch, you are working with instances of materials assigned to objects in your scene. These materials might not be in any of the Material Editor samples.

**Medit Materials**—Contains global material definitions. The Medit Materials branch contains the 24 material definitions in the Material Editor (page 2–1409). When you select materials from this branch, you are working with global material definitions that might not yet be assigned to objects in your scene.

**Objects**—Contains a hierarchy for all the objects in your scene.

When Manual Navigation (page 2–529) is on, many of these categories display a small plus or minus button to expand/collapse the contents.

### Item Categories

Each type of item in the Hierarchy list is represented by an icon. You can use these icons to quickly identify what each item represents.

**Objects**—Branches contain linked descendants of the object. Branches below contain transforms, materials, and modifiers applied to the object, as well as the object’s creation parameters.

**Controllers**—They contain the animation values for parameters and are the only item in the Hierarchy list that can have a track containing keys. Every controller has an individual icon
Examples of controller icons

Certain types of controllers can contain other controllers. Examples of these are Transform Controllers and List Controllers.

Note: Controllers that have been applied to objects via the Animation menu > Controllers or Constraints submenus automatically have list controllers assigned. Controllers assigned using the Track View Controller menu or right-click Assign Controller choice on the quad menu do not apply list controllers automatically.

Maps—Indicates map definitions. All branches below a map definition are part of that map. This includes values used by parametric maps and other map definitions that are part of a map tree.

Modifier—This icon indicate modifiers and space warp bindings. Branches below a modifier contain the modifiers sub-objects and parameters.

Controller Window Right-Click menu

Right-click any item in the Controller window to display the right-click menu (page 2–516). Use \texttt{Alt} + right-click to display an alternate navigation menu.

The Hierarchy right-click menu contains quick-access commands for expanding and collapsing the hierarchy.

Tip: Use \texttt{Alt}+right-click with quad menu tools to expand and collapse selected tracks individually.

Tip: The Hierarchy right-click menu displays commands related to the highlighted item while the \texttt{Alt}+right-click menu displays commands related to the item currently located under your mouse cursor.

Interface

Select All—Selects all tracks that are visible in the Hierarchy list. Collapsed items are not selected.
Select Invert—Inverts the current Hierarchy list selection.

Tip: Inverting an empty selection is the same as selecting all.

Select None—Deselects all visible object tracks in the Hierarchy list. Does not apply to selected objects in the scene (object icons remain highlighted).

Select Children—Selects all objects descending from the selection by highlighting their icon in the Hierarchy list. Collapsed children are also selected.

Tip: You can also select an object’s children by double-clicking its icon.

Expand Objects—Expands only the object branch for all descendants of the selected object. The expanded branches are not selected.

Expand All—Expands all branches for all descendants of the selected object.

Collapse Objects—Collapses only the object branch for all descendants of the selected object.

Collapse Tracks—Collapses all branches of the selected item.

Collapse All—Collapses all branches for all descendants of the selected object.
Auto Expand—Expands the Hierarchy list automatically based on submenu selection choices. Submenu choices are: Selected Objects Only, Transforms, XYZ Components, Limits, Keyable, Animated, Base Objects, Modifiers, Materials, and Children.

Manual Navigation—Turns off Auto Expand. Allows you to manually decide when you will collapse and what you will expand. A small minus button in a circle to the left of an item lets you collapse it. This button disappears when Auto Expand is on and Manual Navigation is off.

Tip: To expand or collapse individual tracks, use Alt-right-click.

Load Animation—Loads XML animation data from files to the highlighted track or tracks. For more information, see Saving and Loading Animation (page 3–472).

If any of the highlighted tracks has child tracks, animation is loaded to those tracks as well.

Save Animation—Saves XML animation data from the highlighted track or tracks to disk files. For more information, see Saving and Loading Animation (page 3–472).

If any of the highlighted tracks has child tracks, animation is saved from those tracks as well.

Properties—Displays the property dialog of a controller, if available. Not all controller use this dialog, and it is unavailable in these cases.

Assign Controller—Displays the Assign Controller dialog, which offers a list of the available controller for that selection.

Copy—Makes a copy of the controller held in the Track View clipboard.

Paste—Pastes the copied controller to another object or track. Copies can be pasted as instances or as unique copies.

Make Unique—Changes an instanced controller into a unique one. Changes made to instanced controller are reflected in all versions of the controller, unique controllers can be individually edited without affecting anything else.

Alt + Right-click Menu

These commands can also be found on the right-click quad menu described above.

Expand Objects—Expands only the object branch for all descendants of the selected object. The expanded branches are not selected.

Note: If you are using Auto Expand (page 2–527) with the Children option turned on, all objects branches are automatically expanded.

Expand Tracks—Expands all branches of the selected item.

Expand All—Expands all branches for all descendants of the selected object.

Collapse Objects—Collapses only the object branch for all descendants of the selected object.

Collapse Tracks—Collapses all branches of the selected item.

Collapse All—Collapses all branches for all descendants of the selected object.
Properties (Track View Hierarchy)

Select All—Selects all tracks that are visible in the Hierarchy list. Collapsed items are not selected.

Select Invert—Inverts the current Hierarchy list selection.
Tip: Inverting an empty selection is the same as selecting all.

Select Children—Selects all objects descending from the selection by highlighting their icon in the Hierarchy list. Collapsed children are also selected.
Tip: You can also select an object’s children by double-clicking its icon.

Select None—Deselects all visible object tracks in the Hierarchy list. Does not apply to selected objects in the scene (object icons remain highlighted).

Properties—See Properties (page 2–519).

Procedures

To display properties for animation controllers:
1. Select the controller track in the Controller Window.
2. On the Controller menu choose Properties. Or you can right-click and select Properties from the Track View quad menu.

To display the properties dialog for a Bezier key:
The Bezier Controller is the default position controller when an object is animated.
1. In the Track View Key window, select an object’s position key.
2. Right-click the key. The controller dialog is displayed. The Key Tangency choices are available from the dialog.
Tip: You can also change tangency handles using the tools in the Key Tangents: Track View toolbar.

To display the Sound Options dialog for adding a sound track:
1. In the Track View Hierarchy, select the Sound item.
2. Right-click and choose Properties. The Sound Options dialog is displayed.
You can use this dialog to assign a sound file to the animation, which can be displayed in Track View or the track bar.

To display the Sound Options dialog for adding a sound track:
1. In the Track View Hierarchy, select the Sound item.
2. On the Tools toolbar, click Properties, or right-click the Sound label and choose Properties. The Sound Options dialog is displayed.
Chapter 12: Animation

Sound Options Dialog

The Sound track in the Track View Controller window contains two sound options. Use the Metronome to generate a series of beeps, or load a sound file to play back.

Sound is one way to provide the timing for your animation. You can scrub the time slider to locate a particular sound, and coordinate your visuals around it.

You can display this dialog by right-clicking the Sound item in the Track View controller window, or by right-clicking a sound track in the Key window.

Procedure

To add a sound track:

1. In the Track View Controller window, right-click a sound item and choose Properties. The Sound Options dialog is displayed.
2. Click Choose Sound, select a sound file, and then click OK.
   A Wave Form branch appears in the Track View Hierarchy. A waveform appears in the Track View Key window.
3. Turn on Real Time in the Time Configuration dialog to hear the sound track when you play your animation.

Audio group

Choose Sound—Displays a file selector where you choose a sound file.

Remove Sound—Deletes the waveform from Track View.

Reload Sound—Reloading the last loaded file. This allows the sound file to be reloaded when it has been changed by another program.

Active—Plays the waveform during animation playback.

Metronome group

The Metronome track produces a regular beat using two tones. You specify three settings in the Sound Options dialog to control the Metronome:

Beats per minute—Sets the frequency of beats. The beats display in the Metronome tracks as black vertical bars. Default=60.

Beats per measure—Sets which beat is emphasized with a higher pitch tone. Emphasized beats display in the Metronome track as black pluses. For example, a setting of 4 generates a higher pitched tone every fourth beat. Default=4.

Active—Plays the beats during animation playback.
Track View Menus

Track View > Menu bar

A menu bar appears at the top of Track View in both Curve Editor and Dope Sheet modes and the expanded track bar layout. The Track View menu bar is contextual; it changes slightly between Curve Editor and Dope Sheet modes.

The commands available on the Track View menus can also be accessed on the Curve Editor and Dope Sheet toolbars. Certain tools, however, appear only on the toolbars, and do not appear in the menus.

Interface

Modes—Lets you choose between Curve Editor and Dope Sheet. See Modes Menu (page 2–521).

Controller—Assigns, copies, and pastes controllers, and makes them unique. Here you also add looping. See Controller Menu (page 2–521).

Tracks—Adds Note and Visibility tracks. See Tracks Menu (page 2–524).

Keys—Adds, removes, slides, and scales keys. Also includes soft selection, align to cursor, and snap frame. See Keys Menu (page 2–524).

Curves—(Curve Editor only) Applies or removes Ease and Multiplier curves. See Curves Menu (page 2–525).

Time—(Dope Sheet only) Adjusts time. See Time Menu (page 2–526).

Options—Controls the behavior (auto-expansion, etc.) of the Hierarchy list window. Also contains controls that improve performance. See Options Menu (page 2–526).

Display—Affects curve, icon, and tangent display. See Display Menu (page 2–530).

View—Contains Pan and Zoom commands. See View Menu (page 2–532).

Utilities—Randomizes or creates out-of-range keys. Also selects keys by time and current value editor. See Utilities Menu (page 2–533).

Modes Menu

<table>
<thead>
<tr>
<th>Track View &gt; Modes menu</th>
</tr>
</thead>
<tbody>
<tr>
<td>Graph Editors menu &gt; Track View - Dope Sheet &gt; Modes menu</td>
</tr>
<tr>
<td>Main toolbar &gt; Curve Editor (Open) &gt; Modes</td>
</tr>
</tbody>
</table>

The Modes menu lets you switch between the Curve Editor and Dope Sheet when working in Track View.

Curve Editor—Displays and allows for editing of animation function curves.

Dope Sheet—Displays animation as a spreadsheet of keys available for editing.

Controller Menu

<table>
<thead>
<tr>
<th>Graph Editors menu &gt; Track View – Curve Editor &gt; Controller menu</th>
</tr>
</thead>
<tbody>
<tr>
<td>Graph Editors menu &gt; Track View – Dope Sheet &gt; Controller menu</td>
</tr>
<tr>
<td>Main toolbar &gt; Curve Editor (Open) &gt; Track View &gt; Controller menu</td>
</tr>
</tbody>
</table>

The Controller menu gives you tools for working with controllers that are assigned to objects or tracks when in the Curve Editor or Dope Sheet.

Assign—Lets you select tracks and then assign a controller to that selection. See Assign Controller (page 2–546).
Delete Controller—Lets you delete certain controllers, that can’t otherwise be replaced (Visibility tracks, Image Motion Blur Multiplier, Object Motion Blur, On/Off). See Delete Controller (page 2–549).

Keyable—Toggles the ability to be keyed of selected controller tracks. Use this with the Show Keyable button on the toolbar to see whether a track is keyable.

Copy—Puts a copy of the selected controller track into the Track View buffer. See Copy Controller (page 2–544).

Paste—Copies the controller track in the Track View buffer onto the selected track of another object or objects. You have the option of pasting as a copy or as an instance. See Paste Controller (page 2–545).

Collapse Controller—Converts procedural animation tracks to Bezier, Euler, Linear, or TCB keyframe controller tracks. Can also be used to convert any controller to these type of controllers. Allows for key reduction by using a Samples parameter. See Collapse Controller (page 2–522).

Enable Anim Layer—Assigns a Layer controller to each highlighted track in the hierarchy window. See Animation Layers (page 2–326).

Note: You must first set keys on the desired tracks before they can be layer-enabled.

Ignore Animation Range—Ignores the animation range for the selected controller track. When set, the track plays independently of its range and its background changes color. See Ignore Animation Range (page 2–549).

Respect Animation Range—Respects the animation range for the selected controller track. When set, the track plays only within its range. See Respect Animation Range (page 2–550).

Make Unique—Lets you turn an instanced controller into a unique controller. If a controller is instanced, making changes to it will affect where ever it is copied. If the controller is unique, then changes to it will not affect anything else. See Make Controller Unique (page 2–550).

Out of Range Types—Lets you extend the animation beyond the existing keyframes. Used primarily to loop and otherwise cycle your animation without having to copy keys. See Parameter Curve Out-of-Range Types (page 2–551).

Properties—Displays the Properties dialog, which gives access to the key interpolation types. Different controller types will offer individual options here. For example a Position XYZ controller will offer Fast, Slow, Linear, Smooth, Step, Bezier and Auto Tangent as key options, while a TCB controller will not show any of those controls. For some controllers this is the primary gateway to the animation parameters. See Properties (Track View Key Window) (page 2–560).

Collapse Controller

The Collapse Controller tool allows you to convert procedural animation tracks into tracks with keyframes. A procedural track is an expression track, wired parameter, noise controller, or even something like a list controller.

You can also use this tool to convert any controller track to a simple keyframed track. You can convert rotation tracks to either Euler or TCB, and collapse Position and Scale tracks to either Bezier or Linear controllers.

You can collapse an entire track, or collapse a range of frames within a track by setting the Start and End frames. A Samples parameter lets you define how many frames will be placed between keys.
Collapse Controller can be used to collapse any number of selected tracks at once.

This functionality is similar to the Collapse button found in the Collapse Transform group of the Motion panel > Trajectories rollout (page 2–301).

**Warning:** If you are using a Path constraint with the Follow option, using Collapse Controller to collapse the position and rotation tracks will not preserve rotation properly, because additional rotation is applied by the Path constraint. If you want to collapse this kind of track, use Collapse in the Collapse Transform group of the Motion panel > Trajectories rollout instead.

**Procedure**

To collapse a procedural controller track:

1. In a viewport, select an object with a procedural controller, then right-click and choose Curve Editor from the quad menu.

   The Track View – Curve Editor is displayed.

2. In the Curve Editor’s Controllers window, select the track you want to collapse. Then choose Controller > Collapse Controller from the Track View menu.

   The Collapse Controller dialog appears.

3. Change the Samples to specify the number of frames between keys.

   The default value of 1.0 creates a key for every other frame, which might be more than you want to work with.

4. Select the type of controller that you want the keys to use after collapsing.

   Position and Scale tracks collapse to either Bezier or Linear. Rotation tracks collapse to either Euler or TCB.

   Note: TCB controllers will not display function curves.

5. Click OK.

The Key window displays the curves for the collapsed animation. The track bar displays the keys, as does the Track View – Dope Sheet.

Tip: If you want to collapse the controller into a weighted list controller, turn on Add To New Layer. The original controller will be stored on a layer with a weight of 0.0. It will have no effect, but will be available for future use, if need be.

**Interface**

![Collapse Controller dialog](image)

- **Start Frame**—Sets the first frame of the range of animation to be collapsed. Default=The first frame of the original controller’s active range.

- **End Frame**—Sets the last frame of the range of animation to be collapsed. Default=The last frame of the original controller’s active range.

- **Warning:** If you choose a range of frames smaller than the original range, the animation within the range will be collapsed, and the remaining motion will be discarded unless Add to New Layer is on.

- **Samples**—Sets the granularity of the collapse operation. This value defines the number of frames between keys. Default=1.0.

- **Collapse to**—Sets the type of controller the procedural track will become:

  - **Bezier or Euler Controller**—When this is chosen, Position, Scale, and scalar parameter tracks will...
be assigned Bezier controllers. Rotation tracks will be assigned Euler controllers.

- **Linear or TCB Controller**—When this is chosen, Position, Scale, and scalar parameter tracks will be assigned Linear controllers. Rotation tracks will be assigned TCB controllers.

  Note: TCB controllers will not display function curves.

  **Add to New Layer**—When this is turned on, the collapsed controller is added as a new layer in a weighted list controller (page 2–342). Default=off.

  This option is useful because it keeps the old controller on another layer with a weight of 0.0. This lets you restore the original animation easily if you need to.

---

**Tracks Menu**

| Graph Editors menu > Track View - Curve Editor > Tracks menu |
| Graph Editors menu > Track View - Dope Sheet > Tracks menu |
| Main toolbar > Curve Editor (Open) > Tracks menu |

There are two types of special tracks that can be accessed from the Tracks menu.

- **Note Track**—Lets you add or remove note tracks to your scene. Note tracks can be used for variety of purposes to add information to any track in Track View. See Add Note Track (page 2–552).

- **Visibility Track**—Lets you add or remove visibility tracks to objects your scene. You can also keyframe visibility by changing the visibility parameter in the Object Properties dialog when Auto Key is on. See Add Visibility Track (page 2–556).

---

**Keys Menu**

The commands on the Keys menu give you control over keys when working in either the Curve Editor or the Dope Sheet.

- **Add Keys**—Adds keys in the Curve Editor or Dope Sheet. See Add Keys (Dope Sheet) (page 2–560).

- **Reduce Keys**—Reduces the amount of keys on curves, or in edit keys mode in Dope Sheet. See Reduce Keys (page 2–572).

- **Move**—Moves keys either vertically (in value) or horizontally (in time). See Move Keys (Dope Sheet) (page 2–558) or Move Keys (Curve Editor) (page 2–579).

- **Slide**—Moves keys, and adjacent keys slide away to make room for the move. See Slide Keys (page 2–558).

- **Scale Values**—Proportionally increase or decrease the key values (in space, not time). Use in combination with the Scale Value Origin Slider. See Scale Values (page 2–581).

- **Scale Keys - Time**—Proportionally increase or decrease the key values (in space, not time). Use in combination with the Scale Value Origin Slider. See Scale Keys - Time (page 2–559).

- **Use Soft Select**—When turned on, affects keys adjacent to a selection set of keys according to a falloff threshold. Works on Curves and Dope Sheet edit keys mode. See Use Soft Select (page 2–525).

- **Soft Select Settings**—Use Soft Select Settings to display the dialog that lets you control the falloff range of the soft selection. Select some keys, then watch the Track View Key window while you adjust the range value. See Soft Selection Settings (page 2–525).
Use Soft Select

Track View > Keys menu > Use Soft Select

When on, Use Soft Select affects keys adjacent to a selection set of keys according to a falloff threshold. This applies to both Curve Editor keys and Dope Sheet Edit Keys modes.

To adjust the Soft Selection range and falloff, choose Soft Select Settings on the Keys menu.

Tip: Keys are “soft-selected” across time only (horizontally).

Procedure

To soft select keys in Track View:

1. In either Dope Sheet > Edit Keys mode or in the Curve Editor, select a single key in the middle of the animation curve or graph.
2. From the Keys menu, choose Use Soft Select.
3. From the Keys menu, choose Soft Select Settings
   The Soft Selection Settings dialog appears.
4. Change the Range and observe the soft selection display in the keys window.

See also

Soft Selection Settings (page 2–525)

Soft Selection Settings

Track View menu bar > Keys > Use Soft Select

Displays a dialog with controls to adjust the range and falloff of the soft selection of keys in the Dope Sheet and Curve Editor.

Interface

Soft—Toggles usage of the soft selection. When this is off, only the selected keys are used, the soft selection is not.
Range—Determines the range of keys affected by the soft selection.
Falloff—Determines the distribution of the strength of the soft selection over the range of keys.

Curves Menu

Graphic Editors menu > Track View - Curve Editor > Curves menu
Main toolbar > Curve Editor (Open) > Curves menu

The Curves menu is only available when working in Track View’s Curve Editor mode. The tools on this menu facilitate curve adjustments.

Apply – Ease Curve—Applies curves to selected tracks that allow you to effect the timing of the animation. See Apply Ease Curve / Apply Multiplier Curve (page 2–584).

Apply – Multiplier Curve—Applies curves to selected tracks that allow you to effect the strength of the animation. See Apply Ease Curve / Apply Multiplier Curve (page 2–584).
Remove—Removes Ease and Multiplier Curves.
See Remove Ease/Multiplier Curve (page 2–585).

On/Off—Turns Ease and Multiplier Curves on or off. See On/Off (Curves) (page 2–585).

**Options Menu**

The Options menu contains a series of toggles and switches that control how items are handled in the Track View window.

Interactive Update (page 2–526)
Sync Cursor Time (page 2–527)
Auto Expand (page 2–527)
Auto Select (page 2–528)
Auto Scroll (page 2–528)
Modify Subtree (page 2–528) (Dope Sheet only)
Modify Child Keys (page 2–529) (Dope Sheet only)
Manual Navigation (page 2–529)

**Interactive Update**

Interactive Update controls whether editing keys in Track View updates the viewports in real time. Also, turning off Interactive Update allows faster animation playback in some cases.

Interactive Update—When on, editing keys in Track View updates the viewports with any changes that affect the current frame while your mouse button is down. When off, the viewports are updated only after you release the mouse button. Default=Off.

For example, if you’re at frame 10 and there are position keys at frame 0, 20, 30, and 50, then editing either a key at frame 0 or 20 with Interactive Update on potentially lets you see the changes in the viewport as you drag the key. However, editing a key at frame 50 is unlikely to cause a position...
change at the current frame, so you won’t see any difference with Interactive Update on or off.

To view the results of editing keys anywhere in Track View in real time, use Sync Cursor Time (page 2–527) instead. Turning on Sync Cursor Time automatically turns on Interactive Update as well, so you can see all changes interactively.

Keep this turned off when you are working in big files and moving large numbers of keys. Default=Off.

In some circumstances, simply playing back an animation or dragging the time slider with Track View open, without editing keys, can cause performance issues. If you experience this, and Interactive Update is on, turn it off to improve playback performance.

**Sync Cursor Time**

Track View > Options menu > Sync Cursor Time

*Sync Cursor Time*—Snaps the time slider to the cursor position. When on, clicking the cursor in the Track View window moves the time slider to that spot in time. When you release the mouse button, the time slider jumps back to its previous position.

When off, the time slider does not jump to the cursor position; you need to click the time slider and move it by hand. Default=Off.

Turning on Sync Cursor Time also turns on Interactive Update (page 2–526) so you can edit keys anywhere in Track View by dragging them and see your results right away. The time slider jumps to the frame at which the key resides and the viewport displays your changes in real time.

**Auto Expand**

Track View > Options menu > Auto Expand submenu

Auto Expand determines the behavior of the controller window display based on choices made from a submenu. To turn Auto Expand off with a single click, choose Manual Navigation from the Options menu: The Auto Expand settings are then disregarded.

When you are working on a specific animation task, turn off the unnecessary options to focus the controller window on what you need to see.

Note: The default auto-navigation setting for the Dope Sheet editor auto-expands only to the node track for the currently selected object. This reduces the number of tracks whose keys need to be displayed and also helps enforce the top-down workflow for which the Dope Sheet editor is designed.

**Interface**

*Selected Objects Only*—When this is on, the controller window displays the tracks for highlighted objects only. Default=On.

*Transforms*—Expands the Hierarchy list to display the highlighted object’s Transform track. Default=On.

*XYZ Components*—Expands the highlighted object’s Transform track to display individual XYZ components contained in each Transform controller (such as Position and Scale).

*Limits*—Expands the highlighted object’s Limits track to display its parameters (such as Upper Limit and Lower Smoothing). To be used in conjunction with the Limit Controller (page 2–335). Default=On.

*Keyable*—Expands the highlighted object’s Hierarchy list to display keyable tracks. You must
also enable Transform or XYZ Components to see results. Also expands the Environment and Global Shadow Parameters Hierarchy lists.

**Animated**—Expands the highlighted object’s Hierarchy list to display animated tracks.

**Base Objects**—Expands the highlighted object’s base object track to display its parameters (such as Height/Width/Length).

**Modifiers**—Expands the highlighted object’s modifier track to display modifiers applied to that object.

**Materials**—Expands the highlighted object’s material track to display materials parameters.

**Children**—Expands the Hierarchy list to display all children starting from the highlighted object.

**Auto Select**

**Auto Scroll**

Track View > Options menu > Auto Scroll submenu

Provides options to control the automatic scrolling of the controller window in Dope Sheet and Curve Editor. When these are chosen, the choice is displayed at the top of the controller window.

Options include Selected and Objects.

**Interface**

**Selected**—When this is on, the controller window automatically scrolls to move the viewport selection to the top of the controller window.

**Objects**—When this is turned on, the controller window automatically scrolls to show all the objects in the scene in the controller window.

**Modify Subtree**

Modify Subtree lets you move and scale on all sub-tracks for any/all tracks on a node. It has two modes: Edit Keys and Edit Ranges.

**Note:** *Modify Child Keys (page 2–529)* works similarly, but for child nodes of the current object. Modify Subtree lets you edit timing for a subset of tracks for an object, while Modify Child Keys lets you edit the timing of an entire linked structure, group, or character.
Procedure

To drag the ranges and linked descendants of an object:

1. In the Dope Sheet Editor, click Edit Ranges.
   Modify Subtree is on by default.

2. Drag the World range bar or the Objects range bar.
   With Modify Subtree on, a range bar is displayed in the Objects branch. The Objects branch is the default parent of all named objects in the scene.
   Dragging a parent Objects range bar with Modify Subtree on affects all tracks subordinate to the object and all tracks of its linked descendants.
   Dragging the World range bar with Modify Subtree on affects all tracks in the scene, including Sounds, Materials, and all tracks of all objects.

3. Turn Modify Subtree off.
   The World range bar and the Objects range bar are no longer available. In this mode you can affect the range of an individual object or track without affecting its descendants.

Interface

Modify Subtree (Edit Keys)—Edits (cuts, pastes, or moves) keys in the parent track. Anything you do to the keys in the parental track affects the child keys as well.
Note: Adding keys only affects the current track.

Modify Subtree (Edit Range)—Affects the tracks of an object and all of its descendant objects. When you edit the range of a parent object, the child objects are also affected.

Modify Child Keys

Track View - Dope Sheet > Options menu > Modify Child Keys

Track View - Dope Sheet > Track View toolbar > Modify Child Keys button

Provides the ability to turn changes on and off down the hierarchy when working in Dope Sheet mode. Changes that you have made to a parent object can be added to the children by clicking this toolbar button. Similarly, if you have made changes with Modify Subtree on, and you want to remove the changes from the children, clicking Modify Child Keys will remove those changes from the children that you previously made to the parent.

This tool is primarily designed for use in Dope Sheet Edit Ranges mode.

Modify Subtree allows you to move, scale, edit time, and so on, on all sub-tracks for any or all tracks on a node. Modify Child Keys does the same thing, but also extends to child nodes as well. Modify Subtree lets you edit timing for an object of subset of tracks on an object, while modify child keys lets you edit the timing of an entire linked structure, group, or character.

Manual Navigation

Main toolbar > Curve Editor (Open) > Options menu > Manual Navigation

Graph Editor > Track View - Curve Editor > Right-click the controller window. > Manual Navigation.

Manual Navigation turns off the Auto Scroll features of the controller window and allows you
to select which tracks will display on an individual basis.

The default behavior of the Controller window is to automatically display the selected object animated tracks, and to hide them when the object is not selected in the viewport. Turning on Manual Navigation changes this behavior so that deselecting the object will not make the curves disappear from view.

When Manual Navigation is engaged, buttons appear in the Controller window next to the tracks, that allow you to expand or collapse individual containers such as objects or materials.

Tip: Use [Alt]+right-click to quickly access tools for expanding and collapsing selected tracks.

To collapse individual components in the Controller window:

1. On the Graph Editors menu, choose Track View - Curve Editor.
2. Right-click the controller window and turn on Manual Navigation.
3. Click any item label in the controller window.
   An small minus sign within a circle appears to the left of the entry.
4. Click the minus sign in the circle.
   The tracks collapse. A plus sign within a circle appears.

When Manual Navigation is turned off, tracks expand based on Auto-Expand choices made on the Settings > Auto Expand menu.

---

### Display Menu

Display Menu

Track View > Curve Editor > Display menu

Display is only available when Track View is in Curve Editor mode. The toggles in the Display menu let you adjust and customize how the items in the Curve Editor appear.

- **Selected Key Stats**—Displays the statistics for the selected keys in the function curve window. This is useful because you only see statistics for the keys you are working on. See Show Selected Key Statistics (page 2–595)
- **All Tangents**—Displays all the tangent handles for all keys in the Curve Editor.
- **Custom Icons**—Changes the display of the icons in the Hierarchy list from 2D to 3D shaded.
- **Keyable Icons**—Displays a keyable icon that lets you define if a track is keyable or not. Red icons are keyable tracks, Black icons are not. Click the icon to toggle between these or use Keyable on the Controllers menu. See Keyable Icons (page 2–531).
- **Hide Non-Selected Curves**—When this is on, if you deselect the object in the viewport, the function curve will also disappear from view in the Curve Editor. Default is on. See Hide/Show Non-Selected Curves (page 2–532).
- **Show Non-Selected Curves**—Turn this on so you can deselect an object in the viewport and still see its curves. Default is off. See Hide/Show Non-Selected Curves (page 2–532).
- **Freeze Non-Selected Curves**—Displays nonselected curves, but doesn’t allow you to edit them. Only available when Show Non-Selected Curves is on. Default is on. See Freeze Non-Selected Curves (page 2–587).
**Filters**—provides controls to filter the display in Curve Editor. There are a wide range of options to show, hide and display. See Filters (page 2–541).

---

**Show All Tangents**

- Track View > Curve Editor toolbar > Show All Tangents
- Curve Editor menu bar > Display > All Tangents

This feature shows all tangent handles on any displayed curves.

You can make changes to multiple tangent handles simultaneously by using Show All Tangents in combination with Lock Tangents.

**See also**

*Show Tangents* (page 2–582)

---

**Keyable Icons**

- Main toolbar > Curve Editor (Open) > Display menu > Keyable Icons
- Menu bar > Graph Editors > Track View - Curve Editor > Track View toolbar > Show Keyable Icons

Keyable icons provide a method to tag a track so that it can receive keyframes or be exempted from keyframes. An icon is displayed in the Controller window next to the name of track to indicate whether or not the track is keyable. You can toggle the state of the icon to define the keyable property.

You can also use the Track View Controller menu > Keyable command to make tracks keyable in a single operation.

You can define keyboard shortcuts for making tracks keyable. By combining the use of keyable icons with key filters, you can use Set Key animation mode to add keyframes to just the tracks you want to work with, and avoid keyframing other tracks.

**Scale**

Red key icon means a track is keyable.

When the keyable icons are visible, click the red icon to turn off the track.

**Scale**

Black key in a circle indicates a track is not keyable.

**Warning:** When you are working with Set Key animation and you have used key filters to select object parameters or materials, all of the parameters will be keyed unless you turn off the track’s keyable property.

**Tip:** You can assign a keyboard shortcut for making tracks keyable, by choosing Keyable Property Toggle in the Track View group, on the Keyboard panel of the Customize User Interface dialog.

**Procedures**

**To make an individual track keyable:**

1. Select the object in the viewport.
2. Right-click and choose Curve Editor.
   
   The Function Curve Editor opens, with the selected object tracks visible.
3. On the Track View toolbar, click Show Keyable Icons.
4. Click the red keyable icons for the tracks for which you want to prevent animation.
   
   The tracks are changed, now marked with a black key in a circle. These tracks will not receive keyframes. Only the tracks marked with red keyable icons will.

   **Note:** Keyable tracks work with both Auto Key and Set Key animation modes.

**To make multiple tracks keyable:**

1. In Track View, with the object selected, hold down the [Ctrl] key and click each track to
create a selection set of tracks for which you want to prevent animation. This can be for one or multiple objects.

Tip: You can hold down the Shift key to select a group of sequential tracks at once. Alternately you can hold down the Alt key to select all tracks at the same level as a given track at once.

Note: If you select just a parent track such as Position, Controller > Keyable will toggle all of its sub-tracks, even if they’re not selected.

2. From the Controller menu, choose Keyable.

The selected tracks are now defined as keyable.

3. From the Display menu, choose Keyable Icons.

The keyable icon appears next to the tracks.

The icon appears red for the tracks that are keyable, and black for the ones that are not.

Tip: Use the same procedure to make multiple tracks not keyable. The Controller > Keyable command toggles the keyability of the tracks.

Note: If you have a mixed keyable situation it will toggle the state of the first track and then set all remaining tracks to match the value of the first track.

If you turn on Show Non-Selected Curves, then you can also use Freeze Non-Selected Curves. This allows you to see the other curve but not edit it inadvertently.

---

**View Menu**

These commands replicate those found on the Navigation toolbar in Track View.

- **Pan**—Lets you move the window. See *Pan (Track View)* (page 2–595).
- **Zoom**—Lets you zoom in and out. See *Zoom Track View Key Window* (page 2–596).
- **Zoom Region**—Lets you zoom in to a rectangular area. See *Zoom Region (Track View)* (page 2–597).
- **Zoom Horizontal Extents**—Zooms to the active time segment. See *Zoom Horizontal Extents* (page 2–595).
- **Zoom Horizontal Extents Keys**—Zooms to show all keys. See *Zoom Horizontal Extents* (page 2–595).
- **Zoom Value Extents**—(Curve Editor only) Zooms vertically so that you can see the full height of the curve.
- **Zoom Values**—(Curve Editor only) Zooms the contents of the keys window vertically. Drag upward to increase magnification, or downward to decrease magnification.

---

**Hide/Show Non-Selected Curves**

These commands either hide or show function curves that are not selected in the controller window.

When Hide Non-Selected Curves is on (the default), the curve will disappear when another track is chosen.

When Show Non-Selected Curves is on, the curve will still be visible in the Key window when another track is chosen.
Utilities Menu

Graph Editors menu > Track View - Curve Editor > Utilities menu

Graph Editors menu > Track View - Dope Sheet > Utilities menu

Main toolbar > Curve Editor (Open) > Utilities menu

The Utilities menu (page 2–561) gives you access to the Track View Utilities dialog. The dialog shows a list of tools you can use when working with keys. This menu is available in both Curve Editor and Dope Sheet modes.

Randomize Keys—Changes the values of selected keys randomly based on range thresholds. Use this on either values or time. For details, see Randomize Keys Utility (page 2–562).

Create Out of Range Keys—Creates new keys for selected tracks based on Out-of-Range Parameters. Adjust the samples value to change the granularity of the key creation. For details, see Create Out of Range Keys Utility (page 2–562).

Select Keys by Time—Allows you to select the keys within a time range. Turn off Clear Previous Selection to create discontinuous selection sets. For details, see Select Keys By Time Utility (page 2–563).

Soft Selection Settings Manager—Displays a soft selection dialog at the bottom of the Track View window. For details, see Soft Selection Settings (page 2–523).

Euler Filter—Corrects rotation anomalies by filtering Euler rotation tracks. For details, see Euler Filter (page 2–564).

Current Value Editor—Provides transform type-in capability from within the Track View modes. Allows you to choose between absolute and relative value editing. The name of the controller appears above the axis choices. For details, see Current Value Editor (page 2–565).
Chapter 12: Animation

This utility starts a floating Current Value window that works for either Dope Sheet – Edit keys mode or Curve Editor. It doesn’t work for Edit Ranges. Not for use with object parameters, the current value editor is intended for use primarily with Transform controllers.

Track View Quad Menu

Right-clicking the Key window or Hierarchy list brings up a quad menu that offers instant access to tools. The menu is context-sensitive, so its contents vary, depending on what is highlighted. For example, when the Hierarchy list is active, you can assign copy and paste controllers, and open properties which you can animate. You can set the Auto Expand and Manual Navigation controls to change the behavior of the Controller window display.

The commands from the alternative quad menu (Alt+right-click) are integrated in the right-click quad menu (page 2–516). The Select, Expand, and Collapse commands are therefore accessible along with the existing quad menu commands, improving workflow efficiency.

Controller window quad menu

When the keys window is active you can draw curves, add keys, move keys and scale values. You can also reduce keys.

Key window quad menu

In the Controller window, if you hold down Alt+right-click you can display an alternate quad menu, which is also integrated with the main quad menu. This menu was available in earlier versions of the program as a default right-click menu in Track View.
You can add additional commands to these quad menus. You can customize the Track View quad menu the same as any other quad menu.

**Procedure**

**To customize the Track view quad menu:**

1. On the Customize menu choose Customize User Interface.
2. On the Customize User Interface dialog, click the Quad tab.
3. From the Quad pull-down menu, choose Track View Quad, or Track View Key Quad.
4. Change the Group to Track View, and then drag items from the table of actions on the left to the window in the lower right.

---

**Key Tools Toolbar**

- **Filter**—Use this to determine what is displayed in the Controller window and the Key window. See Filters (page 2–541).
- **Move Keys**—Moves keys freely both horizontally and vertically on the function curve graph. See Move Keys (page 2–558).
- **Move Keys — Horizontal**—Moves keys only horizontally on the function curve graph. See Move Keys (page 2–558).
- **Move Keys — Vertical**—Moves keys constrained vertically on the function curve graph. See Move Keys (page 2–558).
- **Slide Keys**—Use Slide Keys in the Curve Editor to move a group of keys and slide adjacent keys away as you move. See Slide Keys (page 2–558).
- **Scale Keys**—Use Scale Keys to compress or expand the amount of time between keyframes. Works both in Curve Editor and Dope Sheet modes. See Scale Keys - Time (page 2–559).
- **Scale Values**—Proportionally increases or decreases the values of the keys, rather than moving the keys in time. See Scale Values (page 2–581).
- **Add Keys**—Creates keys on existing curves on the function curve graph or Dope Sheet. See Add Keys (Dope Sheet) (page 2–560).

---

**Track View Toolbars**

**Curve Editor Toolbars**

Main toolbar > Curve Editor (Open) > Curve Editor toolbar

Track View - Dope Sheet > Modes menu > Curve Editor > Curve Editor toolbar

The Curve Editor toolbars contain tools that are also available from the Track View menu bar. The toolbars can be floated, docked, and rearranged as you like. These include the Keys toolbar, The Key Tangents toolbar, and the Curves toolbar, all of which are displayed by default. You can also display other toolbars for quick access to additional tools. To show the hidden toolbars, right-click an empty area between toolbars, choose Show Toolbars, and then pick the toolbar you want to display.
[Image 315x629 to 339x652]

**Draw Curves**—Use this to draw new curves, or revise existing ones by sketching directly on the function curve graph. See *Draw Curves* (page 2–582).

[Image 315x572 to 339x595]

**Reduce Keys**—Use this to reduce the amount of keys in a track. See *Reduce Keys* (page 2–572).

### Key Tangency Toolbar

- **Set Tangents to Auto**—Located on the Key Tangents Track View toolbar, select keys then click this button to set tangents to Auto Tangent automatically. A flyout also lets you set in tangents and out tangents individually to Auto. Selecting the handles of an Auto tangent changes them to custom, and makes them available for editing.

- **Set Tangents to Custom**—Sets keys to custom tangents. Select the key then click this button to make the key handles available for editing. Set in and out tangents individually using the flyout. Use the `Shift` key to break continuity when using handles.

- **Set Tangents to Fast**—Sets key tangency to fast in, fast out, or both in and out, depending on your choice from the flyout.

- **Set Tangents to Slow**—Sets key tangency to slow in, slow out, or both in and out, depending on your choice from the flyout.

- **Set Tangents to Step**—Sets key tangency to step in, step out, or both in and out, depending on your choice from the flyout. Use step to freeze motion from one key to the next.

### Curves Toolbar

- **Set Tangents to Linear**—Sets key tangency to linear in, linear out, or both in and out, depending on your choice from the flyout.

- **Set Tangents to Smooth**—Sets key tangency to smooth. Use this to even up discontinuous motion.

- **Lock Selection**—Locks the key selection. Once you have created a selection, turn this on and you can’t inadvertently select something else. See *Lock Selection* (page 2–555).

- **Snap Frames**—Restricts key movement to frames. Keys that are moved will always snap to frames when this is on. When this is off, you can move a key so it falls between frames and becomes a sub-frame key. Default=on. See *Snap Frames* (page 2–554).

- **Parameter Out-of-Range Curves**—Use this to repeat keyframed motion beyond the range of the keys. Includes options for Loop, Ping Pong, Cycle, or Repeat relatively, as well as constant and linear. If you use Parameter Out-of-Range types, you can later create keys using Track View > Utilities > Create Out-of-Range Keys. See *Parameter Curve Out-of-Range Types* (page 2–551) and *Create Out of Range Keys Utility* (page 2–562).

- **Show Keyable Icons**—Displays an icon that defines a track as keyable or not. Use this to set keys only on the tracks you want to keyframe. Turning off a track in Track View also restricts the movement in the viewport. Red keys indicate keyable tracks, black keys are not keyable. See *Keyable Icons* (page 2–531).
Show Tangents—Hides or displays tangent handles on the curves. Use this to hide the handles on individual curves. See Show Tangents (page 2–582).

Show All Tangents—Hides or displays all tangent handles on the curves. Use this to hide the handles quickly when many keys are selected. See Show All Tangents (page 2–531).

Lock Tangents—Locks the selection of multiple tangent handles, so you can then manipulate several handles at once. When Lock Tangents is off, you can only manipulate one key tangency at a time. See Lock Tangents (page 2–583).

Biped Toolbar
These tools let you choose which animation curves to display in the Curve Editor. You can toggle between the position and rotation curves, as well as toggle the separate curves representing the X, Y, and Z axes of the current biped selection.

Show Biped Position Curves—Displays the position curves for the animated biped selection. Also chooses Pos Curve from the Curve Type drop-down list of the Animation Workbench Toolbar (page 2–1014).

Show Biped Rotation Curves—Displays the rotation curves for the animated biped selection. Also chooses Rot Curve from the Curve Type drop-down list of the Animation Workbench Toolbar (page 2–1014). Default=on.

Show Biped X Curves—Toggles the X axis of the current animation or position curves. Also toggles the X button of the Animation Workbench Toolbar (page 2–1014). Default=on.

Show Biped Y Curves—Toggles the Y axis of the current animation or position curves. Also toggles the Y button of the Animation Workbench Toolbar (page 2–1014). Default=on.

Show Biped Z Curves—Toggles the Z axis of the current animation or position curves. Also toggles the Z button of the Animation Workbench Toolbar (page 2–1014). Default=on.

Name: Track View Toolbar

Name—Track View lets you name the Track View. By entering a name in this field, you create a named Track View that you can recall using the Graph Editors menu > Saved Track View submenu. Also available in Dope Sheet mode.

Track Selection Toolbar

Zoom Selected Object—Puts the currently selected object at the top of the Hierarchy list. Also available in Dope Sheet mode. See Zoom Selected Object (page 2–588) for details.

Note: If multiple objects are selected, the Hierarchy list zoom is based on an alphabetical sorting.

Select By Name—Highlights filtered tracks in the Controller window based on the current field value. Also available in Dope Sheet mode. See Select By Name (page 2–589) for details.
Tip: You can use commas (,) to include multiple names in your selection.

**Track Set List**—Allows you to assign a name to the current track selection (referred to as a track set), and then later reselect those tracks by choosing the respective track set from the list. Also available in Dope Sheet mode. See *Track Set List* (page 2–590) for details.

You can edit track set lists via the Edit Track Set button, which opens the *Track Sets Editor dialog* (page 2–591).

**Navigation Toolbar**

**Navigation**—Track View provides tools to pan and zoom the Key window. You can zoom to the extents of the time or the values. Also available in Dope Sheet mode. See *Status Bar/View Controls* (page 2–588).

**Key Stats Toolbar**

**Key Stats**—Track View provides tools for the display and type-in transform of key values. Also available in Dope Sheet mode.

---

**Dope Sheet Toolbars**

Main toolbar > Curve Editor (Open) > Modes menu > Dope Sheet > Dope Sheet toolbar

These are the default toolbars that are visible when you open the Dope Sheet.

**Keys: Dope Sheet Toolbar**

- **Edit Keys**—Displays a Dope Sheet Editor mode that shows the keys as boxes on a graph. Use this to mode to insert, cut, and paste time. See *Edit Keys* (page 2–554).
- **Edit Ranges**—Displays a Dope Sheet Editor mode that shows the keyed tracks as range bars. See *Edit Ranges* (page 2–573).
- **Filter**—Use this to determine what is displayed in the Controller window and the Dope Sheet - Key window. See *Filters* (page 2–541).
- **Slide Keys**—Use Slide Keys in the Dope Sheet to move a group of keys and slide adjacent keys away as you move. Only slides keys on the same controller track. See *Slide Keys* (page 2–558).
- **Add Keys**—Creates keys on existing tracks on the Dope Sheet grid. Combine this tool with Current Value editor to adjust the key values numerically. See *Add Keys (Dope Sheet)* (page 2–560).
- **Scale Keys**—Use Scale Keys to compress or expand the amount of time between keyframes. Works both in Curve Editor and Dope Sheet modes. Uses the time slider as an origin point to or from which to scale. See *Scale Keys - Time* (page 2–559).
**Time: Dope Sheet Toolbar**

- **Select Time**—Lets you select a time range. Time selections include any keys that might be included within the time range. Use Insert Time, then Select Time to choose the time range. See *Select Time* (page 2–566).

- **Delete Time**—Removes selected time from the selected tracks. Cannot be applied globally to shorten the time segment. This removes keys but leaves “blank” frames behind. See *Delete Time* (page 2–567).

- **Reverse Time**—Reverses the keys on selected tracks within a selected time segment. See *Reverse Time* (page 2–569).

- **Scale Time**—Scales the keys within a selected time segment for selected tracks. See *Scale Time* (page 2–570)

- **Insert Time**—Allows you to insert a range of frames as a time insertion. Existing keys slide out of the way to make room for inserted time. Once you have made a time selection with Insert Time, you can then use all the other time tools. See *Insert Time* (page 2–570).

- **Cut Time**—Deleting time selections from the selected tracks. See *Cut Time* (page 2–567).

- **Copy Time**—Duplicates the selected time selection so it will be available for pasting. See *Copy Time* (page 2–568).

- **Paste Time**—Adds cut or copied time selections into the selected tracks. See *Paste Time* (page 2–568).

**Display: Dope Sheet Toolbar**

- **Lock Selection**—Locks the key selection. Once you have created a selection, turn this on so that you cannot inadvertently select something else. See *Lock Selection* (page 2–555).

- **Snap Frames**—Restricts key movement to frames. Keys that are moved will always snap to frames when this is on. When this is off you can move a key so it falls between frames and become a sub-frame key. Default=on. See *Snap Frames* (page 2–554).

- **Show Keyable Icons**—Shows an icon that defines a track as keyable or not. Use this to set keys only on the tracks you desire to keyframe. Turning off a track in Track View will also restrict the movement in the viewport. Red keys show keyable tracks, black keys are not keyable. See *Keyable Icons* (page 2–531).

- **Modify Subtree**—When this is on, allows key manipulations to parent tracks to affect the tracks down the hierarchy. On by default in Dope Sheet mode. See *Modify Subtree* (page 2–528).

- **Modify Child Keys**—If you modify the parent without Modify Subtree on, click Modify Child Keys to apply the change to the child keys. Similarly, if you modify the parent with Modify Subtree on, Modify Child Keys toggles those changes off. See *Modify Child Keys* (page 2–529).

**Name: Track View Toolbar**

- **Name**—Track View
Name—Lets you name the Track View. By entering a name in this field, you create a named Track View window that you can later recall using the Graph Editors menu > Saved Track View submenu. Also available in Curve Editor mode.

Track Selection Toolbar

Zoom Selected Object—Puts the currently selected object at the top of the Hierarchy list. Also available in Curve Editor mode. See Zoom Selected Object (page 2–588) for details.

Note: If multiple objects are selected, the Hierarchy list zoom is based on an alphabetical sorting.

Select By Name—Highlights filtered tracks in the Controller window based on the current field value. Also available in Curve Editor mode. See Select By Name (page 2–589) for details.

Tip: You can use commas (,) to include multiple names in your selection.

Track Set List—Allows you to assign a name to the set of currently highlighted tracks (referred to as a track set), and then later re-select those tracks by choosing the respective track set from the list. Also available in Curve Editor mode. See Track Set List (page 2–590) for details.

You can edit track set lists via the Edit Track Set button, which opens the Track Sets Editor dialog (page 2–591).

Navigation Toolbar

Navigation—Track View provides tools to pan and zoom the Key window. You can zoom to the extents of the time or the values. Also available in Curve Editor mode. See Status Bar/View Controls (page 2–588).

Key Stats Toolbar

Key Stats—Track View provides tools for the display and type-in transform of key values. Also available in Curve Editor mode.

Controller Toolbar

This toolbar contains the basic tools you need to work with controllers in Track View. This toolbar is hidden as a default. Right-click the Track View toolbar and choose Show Toolbars > Controllers: Animation Editor. All of these commands are always available via the Track View Controller menu.

Filters—Click to display the Filters dialog (page 2–542), which you can use to control what Track View displays in the Controller and Key windows.

Copy Controller—Use this to copy a controller and its animated tracks from a selected object.

Paste Controller—Pasts the copied or cut controller onto a new object or selection of object tracks.
Assign Controller—Use this to assign a new controller to an object. All objects have a default controller assigned; use this to change the default controller to a different one. Select the controller track in the Controller window, then use Assign Controller to select a new one.

Delete Controller—Delete a controller from an object. The controller will be replaced with a default controller.

Make Controller Unique—Changes an instanced controller to a unique controller. This lets you make changes to the controller without affecting any other object tracks.

Procedure
To display the Controller toolbar:
1. Right-click the blank area on the Track View toolbar, to the right of the Modify Child Keys button.
2. From the right-click menu, choose Show Toolbars.
3. Choose Controllers: Track View from the list.

Ranges: Dope Sheet Toolbar

Main toolbar > Curve Editor (Open) > Mode > Dope Sheet > Right-click the blank area of the toolbar to the right of Modify Child Keys. > Show toolbar > Extras: Dope Sheet toolbar

This toolbar, hidden by default, provides tools you use when working with ranges.

Edit Ranges—Changes Dope Sheet to display range bars rather than tracks of keys. See Edit Ranges (page 2–573).

Position Ranges—Adjusts the relationship between a range bar and its keys. Turning this on will allow you to see the keys while moving the range bar.

Recouple Ranges—Resizes the range bar to fit the first and last key of the selected track.

Extras: Dope Sheet Toolbar

Provides extra tools for use in Dope Sheet mode.

Exclude Left End Point—Prevents a key at the first frame of a selected block of time from being copied to the clipboard.

Exclude Right End Point—Prevents a key at the last frame of a selected block of time from being copied to the clipboard.

Filters

Main toolbar > Curve Editor (Open) > Track View toolbar > Filters

Graph Editors menu > Track View - Curve Editor/Track View - Dope Sheet > Track View toolbar > Filters

Graph Editors menu > Track View - Curve Editor/Track View - Dope Sheet > Track View menu > Display > Filters

Filters lets you determine which categories of items appear in Track View. When you click the Filters button, Track View’s Filters dialog (page 2–542) is displayed.
You can also right-click the Filters button for quick selection of items.

Tip: You can set up a default filter configuration. Open a single Track View, set the filters the way you want them to come up, and close the Track View. Save the (empty) scene as maxstart.max. This scene file is automatically loaded when you start the program.

Procedures

To position a selected object at the top of the Track View Hierarchy:
1. In a viewport, right-click a selected object.
2. From the right-click menu, choose Curve Editor or Dope Sheet.
   Track View opens with the selected object at the top of the Track View Hierarchy.

To display the animated transform tracks for an object in Track View:
1. Select an object, then open a Track View window.
2. Right-click Filters.
3. From the right-click menu, choose Animated Tracks Only.
4. Right-click Filters again.
5. From the right-click menu, choose Selected Objects Only.

Interface

See Filters Dialog (page 2–542).

Filters Dialog (Track View)

You use the Filters dialog to choose what to display in Track View. For example, you can limit the view to animated tracks only, or tracks for selected objects. This dialog also controls function curve display and transform display for Position, Rotation, Scale, and X, Y, and Z axes individually.

Procedure

To choose filter options:
1. On the Track View toolbar, click Filters.
2. Choose any of the filter options from the dialog.

Interface

Show group
The Show group has options to display any of the following in the Hierarchy list window:
- Hierarchy
- Objects
- Space Warp Bindings
Filters Dialog (Track View)

- Transforms (Position, Rotation, Scale, X/Y/Z/W axes in any combination)
- Modified Objects
- Base Objects
- Controller Types (off by default)
- Note Tracks
- Visibility Tracks
- Sound
- Materials/Maps
- Material/Parameters
- Static Values
- Global Tracks: non-object tracks

All—Sets all Show check boxes to on.
None—Sets all Show check boxes to off.
Invert—Reverses the state of all Show check boxes.

Hide by Controller Type group

Hide By Controller Type contains a window displaying a list of all controller types in 3ds Max. Choose one or more controller types to prevent them from appearing in the Hierarchy list. You can use the standard multiple-selection methods of Ctrl+click, Shift+click, or drag.

All/None/Invert—Selects either all items in the list, none of the items in the list, or inverts the current selection.

Note: When you hide a controller, its subcontrollers (if any) are hidden as well. For example, if you hide a PRS Transform controller, its Position, Rotation, and Scale controllers are also hidden.

Show Only group

- Animated Tracks—Displays only tracks that contain animation. Only the animated tracks are shown, each with its full hierarchy, whether or not the Hierarchy switch is on.

Selected Objects—Displays only items for objects selected in the scene. As you select objects in the scene, the display in the Hierarchy list changes to show the current selection. The display of sound and materials branches are not affected by this filter.

Selected Tracks—Displays only items that you select prior to setting this filter. All of the displayed items are left-justified in the Hierarchy list regardless of their level in the hierarchy.

Visible Objects—Determines whether objects that are hidden in the viewports will appear in the Track View Hierarchy. This does not consider objects with tracks, but only objects that have been hidden. Default=on.
**Keyable Tracks**—Displays only tracks that can receive keys. This property is toggled using the Keyable property available on the Track View Controller menu, or by clicking the keyable icon displayed using Show Keyable Icon. Default=off.

**Active Layer**—For each object listed in the hierarchy window with animation layers (page 2–326) enabled, displays only the active layer, along with all nested controllers.

Tip: Newly available in Customize User Interface (page 3–792) are actions and icons for all six Show Only options. Find them in the Track View group; their names all start with “Filter”.

**Hide by Category group**

Contains a list of check boxes that let you hide tracks based on categories similar to those found in the Display panel. Turning on one of these hides the entire category type and any subcomponents.

**Function Curve Display group**

Check boxes in this group, when active, specify which transforms are suppressed, for which axis, and which RGB color values are suppressed. This is only used for controllers such as the Bezier Position controller that displays all three axis with one track selected.

Note: The “W” and “A” Filters are for use with the Point4 controller. The W is simply a fourth filter for position, and the A is for use with the floating-point RGBA controller, which is based on the Point4 controller.

**Copy Controller**

Copy Controller copies the selected item to the Track View clipboard.

You can use Copy and Paste to copy object and modifier tracks, controllers, objects, and containers, depending on what you are working on.

The Controller tools are also available as buttons on the Controllers: Track View toolbar. This toolbar is hidden by default; to unhide right-click the toolbar and choose Show Toolbars > Controllers: Track View.

Not all tracks can be copied and pasted. The basic restrictions for using Copy and Paste in Track View are:

- Only a single selected item can be copied.
- A copied item can only be pasted into another item of the same type.
A copied item can be pasted into a selection of multiple items only if all of the items are of the same type.

 Procedures

To copy and paste a modifier:

1. In the Track View Hierarchy, highlight a modifier track.
2. From the Controller menu, choose Copy.
3. Click the object track for an object in the Track View Hierarchy.
4. From the Controllers menu, choose Paste.
   The Paste dialog is displayed.
5. Set the options in the Paste dialog, and click OK.
   The pasted modifier is inserted above the object track you selected. Note that it does not replace any of the tracks in the target object.

To copy and paste a controller:

1. In the Track View Hierarchy, highlight a controller track.
2. On the Track View Controllers menu, click Copy Controller.
3. Highlight the controller track for an object in the Track View Hierarchy.
   Make sure you choose the same type of transform that you copied.
4. From the Controllers menu, choose Paste.
   The Paste dialog is displayed.
5. Set the options in the Paste dialog, and click OK.
   The controller is pasted onto the selected object.

 Paste Controller

Main toolbar > Curve Editor (Open) > Highlight the track you want to paste to. > Controller menu > Paste.

Main toolbar > Curve Editor (Open) > Highlight the controller track in the controller window. > Right-click any blank space on the Track View toolbar > Show Toolbars > Controllers: Track View toolbar > Paste Controller

Keyboard > Ctrl+V

The Paste controller pastes the contents of the Copy Controller buffer. You can use the Copy and Paste buttons to copy tracks, controllers, objects, and containers.

All the Controller tools can also be found on the Controllers: Track View toolbar, which is hidden by default. Right-click the toolbar, then choose Show Toolbars > Controllers: Track View to display the icons for Assign, Copy, Paste, Delete Controller, and Make Controller Unique.

Tip: If you need a gizmo to follow a dummy object, use Copy Controller and Paste Controller to copy the animation from the dummy to the gizmo.

Procedures

See Copy Controller (page 2–544).

Interface

Paste Controller—Paste an item from the Track View clipboard.
The Paste dialog contains the following options:

**Copy/Instance**—Determines whether the cloned item is a simple copy or an instance of the original.

**Replace All Instances**—When you paste to any track that contains an instanced object, replaces all instances of the object with the object on the clipboard. If off, only the object in the selected track will be replaced. Any instanced objects will remain as they are.

---

### Assign Controller

Main toolbar > Curve Editor (Open) > Select the controller track in the controller window. > Controller menu > Assign

Main toolbar > Curve Editor (Open) > Select the controller track in the controller window. > Right-click the controller track and choose Assign Controller.

Keyboard > C

Use Assign Controller to assign animation controllers to any animatable parameter or track in Track View.

Animation controllers provide powerful tools for animating all the objects and materials in a scene. For example, rather than keyframing the position of an object in your scene, the object can follow a spline using the Path constraint, react to any animated parameter using a Reaction controller, or move to the beat of music using the Audio controller. You can combine controllers with a List Controller. You can drive a single vertex or control point on a complex object by a variety of controllers.

You can also assign controllers using the right-click menu in the Track View Controller window. Or you can assign controllers in the Motion panel, in Schematic View, and by using the Animation menu.

### Constraints and Controllers

Technically, there is no difference between a controller and a constraint. A constraint is simply a controller that requires the use of a second object. For example, a Path constraint is a controller that requires a spline object for a path.

### Special-Case Controllers

Special-case controllers are not assigned manually with the Assign Controller command. They are applied automatically during certain procedures.

Barycentric Morph Controller is applied by selecting an object and clicking Command panel > Geometry > Compound Objects > Morph.

A Master Point Controller is assigned when animating vertices, control points, or vectors in the sub-object mode of an Editable Mesh, Editable Spline, Editable Patch, NURBS surface, or FFD modifier.

Slave Controllers can be assigned manually, but is also automatically applied to selected tracks when a Block controller is created in Track View Global Tracks. A Slave controller transfers key data to a Block controller. Slave controllers are described in the Block controller topic.

### Available Animation Controllers and Constraints

**Attachment Constraint (page 2–393):** A Position controller that attaches an object’s position to a face on another object. The target object doesn’t have to be a mesh, but must be able to convert itself to a mesh.

**Audio Controller (page 2–309):** Animates a parameter or object using a sound file.

**Bezier Controller (page 2–310):** Smooths function curves between transform keys, giving the effect of continuous, natural movement. The Bezier
controller is the default controller for position and scale.

_Barycentric Morph Controller (page 2–309):_ Applied during the creation of a morph object. Each morph key represents a series of weights for all morph targets.

_Block Controller (page 2–313):_ Group tracks from multiple objects into Blocks. Blocks can be copied, pasted, scaled, and saved. Use Blocks to quickly re-create a complex motion anywhere in an animation.

_Color RGB Controller (page 2–317) (Point 3 XYZ Controller):_ Creates separate tracks for red, green, and blue.

_Euler XYZ Rotation Controller (page 2–318):_ Combines separate, single-value float controllers to specify an angle of rotation about each of the X, Y, and Z axes. You can specify the order the axes are rotated.

_Expression Controller (page 2–320):_ Mathematical expressions control object parameters such as length, width, and height, or transform and modifier values, such as position coordinates.

_IK Controller (page 2–440):_ Assigned to a hierarchy through the use of an IK Solver. Can be automatically assigned to bones at the time of creation by using Assign to Children.

_Linear Controller (page 2–341):_ Makes the function curves between each of the keyframes into straight lines.

_List Controller (page 2–342):_ Combines controllers.

_Link Constraint (page 2–403):_ Animates the transfer of hierarchical links from one object to another. You can, for example, have the same object passed from object to object.

_LookAt Constraint (page 2–406):_ Forces that object to constantly look at another. Formerly a Transform controller, this is now a rotation controller.

_Master Point Controller (page 2–346):_ Automatically assigned when animating vertices, control points, or vectors in sub-object mode. This controller simplifies managing potentially hundreds of tracks in Track View.

_Motion Capture Controller (page 2–347):_ Controls and records an object’s motion or parameter using an external device. Supported devices are mouse, keyboard, MIDI device, and joystick.

_Noise Controller (page 2–353):_ Generates random values, which you can see as peaks and valleys in the function curve.

_On/Off Controller (page 2–355):_ Provides on and off control.

_Boolean Controller (page 2–316):_ An improved version of the On/Off Controller that allows for adding keys without disrupting the existing keyframing.

_Path Constraint (page 2–398):_ Assigns a spline as a trajectory (path) for an object so that the object follows the path.

_Position XYZ Controller (page 2–356):_ Splits the X, Y, and Z components into three separate tracks.

_PRS Transform Controller (page 2–357):_ Creates subcontrollers for position, rotation, and scale.

_Reaction Controller (page 2–358):_ Allows an object or parameter to react to another object or parameter. For example, you can change the scale of one object based on the Z position of another object.

_Scale XYZ Controller (page 2–371):_ Provides separate scale tracks for the X, Y, and Z axes.

_Script Controller (page 2–372):_ Controls objects and parameters with the 3ds Max scripting language.
Spring Controller (page 2–375): Adds secondary dynamics effects to any point or object position.

Smooth Rotation Controller (page 2–374): Creates smooth rotations.

Surface Constraint (page 2–396): Positions an object along the surface of another object.

TCB Controller (page 2–377): Provides Tension, Continuity, and Bias controls for the function curves between keys.

Transform Script Controller (page 2–379): Provides scripted PRS control for objects.

Waveform Controller (page 2–381): A float controller that provides regular, periodic waveforms. For example, blinking lights and rhythmic object motion.

XRef Controller (page 2–383): Lets you externally reference any type of Transform controller from another scene file.

Procedure

To assign an animation controller in Track View:

1. In the Track View Hierarchy, select one or more parameter items of the same type.

2. From the Controller menu, choose Assign.

3. Choose a controller type from the Assign Controller dialog.

   If a parameter has already been animated, then assigning a new controller has one of the following effects:

   • The existing animation values are recalculated to produce a similar animation with the new controller. For example, replacing Position XYZ with Bezier Position closely preserves the animation.

   • The existing animation values are discarded. For example, replacing Smooth Rotation with Noise Rotation discards the Smooth Rotation animation values.

Interface

Assign Controller—Choose a controller type from the Assign Controllers dialog. Depending on the type of track you have selected, the Choose Controller dialog displays a subset of the different types of controllers.
Delete Controller

Main toolbar > Curve Editor (Open) > Select a deletable track in the Controller Window. > Right-click the toolbar > Show Toolbars > Controllers: Track View > Delete Controller.

Main toolbar > Open Track View > Select a deletable track in the Track View Hierarchy. > Right-click on a blank area of the Track View toolbars and choose Show Toolbars > Controllers toolbar > Delete Controller.

Some node subcontrollers can be deleted. Visibility tracks, Image Motion Blur Multiplier, Object Motion Blur, and On/Off are examples of controllers that can be deleted. Most controllers, however, are not deletable.

You can also delete a Visibility track by using Tracks > Visibility Tracks > Remove.

Procedure

To delete a deletable controller:
1. In the Controller window, select a deletable controller.
2. On the Track View Controllers menu, choose Delete Controller.

   The controller is deleted.

   Note: Most controllers cannot be deleted, only replaced. The Delete Controller menu item is available only if the controller track selected is an applicable type.

Ignore Animation Range

Track View > Select a controller track > Controller menu > Ignore Animation Range

Ignore Animation Range allows a parametric, non-keyable controller track to be active throughout the entire length of the animation, independent of the track’s current animation range. Choosing this option changes the track’s background color to purple.

This setting is active by default on all new controller tracks (turn off the Override Parametric Controller Range By Default option in the Animation Preferences (page 3–828) to change it). However, controller tracks from older scenes are set to Respect Animation Range (page 2–550) to maintain their original behavior.

Procedure

Example: To set a controller track to ignore the animation range:
1. Create a sphere.
2. On the Motion Panel > Assign Controller rollout, highlight the sphere’s Position track.
3. Click the Assign Controller button, and then choose Noise Position from the Assign Controller dialog.
4. The Noise Controller dialog opens. Keep the current settings and close the dialog.
5. Select the sphere, and then right-click it. From the quad menu, choose Dope Sheet.
6. Expand the hierarchy items in the Controller window until you find the sphere’s Position track.
7. Drag the track’s range bar until it starts at frame 10.
8. Play the animation.

Because Ignore Animation Range is on by default, the sphere moves randomly even before entering the track’s animation range.
Respect Animation Range

Respect Animation Range constrains a parametric, non-keyable controller track to be active only within the track’s current animation range. Choosing this option changes the track’s background color to gray.

Note: While Ignore Animation Range (page 2–549) is the default setting (turn off the Override Parametric Controller Range By Default option in the Animation Preferences (page 3–828) to change it), controller tracks from older scenes are set to this setting to maintain their original behavior.

Procedure

Example: To set a controller track to respect the animation range:

1. Create a sphere.
2. On the Motion Panel > Assign Controller rollout, highlight the sphere’s Position track.
3. Click the Assign Controller button, and then choose Noise Position from the Assign Controller dialog.
4. The Noise Controller dialog opens. Keep the current settings and close the dialog.
5. Select the sphere, and then right-click it. From the quad menu, choose Dope Sheet.
6. Expand the hierarchy items in the Controller window until you find the sphere’s Position track.
7. On the Controllers menu, choose Respect Animation Range.
   The background color of the track changes to gray.
8. Drag the track’s range bar so it starts at frame 10.
9. Play the animation.
   Because Respect Animation Range is on, the sphere starts moving only when it is within the track’s animation range.

Make Controller Unique

Make Controller Unique converts an instanced clone of a controller to a copy that’s unique to the current object. Objects and modifiers can also be made unique.

The result depends on whether or not the data flow branches at the selected container:

- If the data flow does not branch anywhere below the selected container, nothing happens.
- If the data flow does branch at or below the selected container, the data flow above the branch is split from the current data flow as a unique object. The data flow from the selected container to the master object is copied and attached to the new unique object.

All the Controller tools can also be found on the Controllers: Track View toolbar which is hidden by default. Right-click any blank area of the Track View toolbar, then choose Show Toolbars > Controllers: Track View to display the buttons for Assign, Copy, Paste, Delete Controller and Make Controller Unique.
**Procedure**

**To convert an instanced controller to a unique one:**

1. Select an instanced controller.
2. On the Controllers menu choose Make Unique, or press \[U\] on the keyboard.
   
   **Tip:** If you have instanced modifiers you can make them unique by choosing the modifier in the Modifier Stack, right-clicking and choosing Make Unique.

---

**Parameter Curve Out-of-Range Types**

With Parameter Curve Out-of-Range Types you can specify how an object is to behave outside the range of the keys you’ve defined.

Use Parameters Curve Out-of-Range Types to create loops and cycles. The idea is to create a short pattern of keys that produce an animated effect, and then loop or cycle through those keys throughout the animation.

Using the Parameter Curve Out-of-Range Types dialog, you select from four ways for repeating your animation and two ways for applying a linear value.

**Tip:** Use the *Create Out of Range Keys utility* (page 2–562), found in Track View Utilities, to turn the parameter out-of-range animation into editable keyframes.

**Typical Steps for Using Parameter Out-of-Range Types**

1. Animate an object to loop or cycle.

2. In the Curve Editor select the track you want to loop.
3. Click Parameter Out-of-Range Types to select how your animation behaves outside the time covered by the range bar.
4. Choose the type of out of range type you want in the dialog, then close it and play the animation. The Curve editor will display the loop or cycle with a dotted line.
5. **Tip:** You can create keys from the out of range type by using the Track View Utilities > Create Out of Range Keys.

---

**Procedure**

**To use Parameter Out-of-Range Types to create a loop:**

1. Create a Box primitive on the left side of the Front viewport.
2. Turn on Auto Key and move the time slider to frame 10.
3. Move the box to the right side of the Front viewport.
4. Open Track View, right-click Filters, and then select Animated Tracks Only.
5. Choose the Position track for the box in the Track View Hierarchy, and then click Parameter Curve Out-of-Range types.
6. In the Parameter Curve Out-of-Range Types dialog, select Ping Pong for both the in and out types and then click OK.
7. Click Play in the Viewport Controls.
   
   The box moves back and forth repeatedly.
   
   While the animation is playing, experiment by adjusting the keys in the Curve Editor, or in the Dope Sheet.
Select from the options for repeating your animation and options for applying a linear value.

**Constant**—Holds the value of the end key of the range for all frames. Use constant when you want no animated effect before the first key of the range or after the last key. Constant is the default out-of-range type.

**Cycle**—Repeats the same animation as within the range. If the first and last keys in the range have different values, the animation will show an abrupt "jump" from the last key to the first. Use Cycle when you want an animation to repeat, but do not need the ends to match.

**Loop**—Repeats the same animation as within the range, but interpolates between the last key and first key in the range to create a smooth loop. If the first and last key are both at the extreme ends of the range, Loop will behave exactly like Cycle. If you use Position Ranges to extend the range bar beyond the keys, the added length determines the amount of time used to interpolate between the last key and the first key. Use loop with an extended range bar to produce smoothly repeating animation.

**Ping Pong**—Alternates between a forward and backward repeat of the animation within the range. Use Ping Pong when you want your animation to alternate back and forth.

**Linear**—Projects the animation value along a line tangent to the function curve at the end of the range. Use Linear when you want the animation to enter and leave the range at a constant velocity.

**Relative Repeat**—Repeats the same animation as within the range but offsets each repetition by the value at the end of the range. Use Relative Repeat to create animations that build on each other as they repeat.

---

**Add Note Track**

Main toolbar > Curve Editor (Open) > Modes > Dope Sheet > Edit Keys > Tracks menu > Note Tracks > Add.

With Add Note Track, you can insert a note track below a highlighted track in the Track View Hierarchy. You can make note keys and associated notes at specific time locations to keep track of what keys do. Do this by adding keys in Dope Sheet > Add Keys mode, then right-click a note key to see the Notes dialog. The information you enter will appear in the Key window under the keys.

Any item in the Hierarchy list can have a note track added as a branch below it. You can add a note track to an item in any of the Track View modes.

With Add Note Track, you can insert a note track below a highlighted track in the Track View Hierarchy. You can make note keys and associated notes at specific time locations to keep track of what keys do. Do this by adding keys in Dope Sheet > Add Keys mode, then right-click a note key to see the Notes dialog. The information you enter will appear in the Key window under the keys.

Any item in the Hierarchy list can have a note track added as a branch below it. You can add a note track to an item in any of the Track View modes.

---

**Note track for animation of door opening**

Once you have created a note track for an item, use Add Keys to insert note keys. Use the Notes dialog to edit the notes.

You can have toolbar access to the Note Tracks by unhiding the Tools: Track View toolbar.
Procedures

To add a note track:

1. On the Track View Dope Sheet toolbar, click Edit Keys.
2. Highlight one or more item labels in the Hierarchy list.
3. From the Tracks menu, choose Note Tracks > Add.

A note track is inserted as a branch directly below each highlighted item.

To add a note key to a note track:

1. Select the Note track (in Dope Sheet Edit Keys mode).
2. Click Add Keys.
3. Click a note track in the Keys Window to place a note at that particular frame.

To edit notes:

1. Right-click a note key to display the Notes dialog.
2. Click inside the edit box, and then start typing.

The first line of your note appears as a label to the right of the note key. You should type a short one- or two-word description as the first line of your note. Press \[Enter\] to start the body of the note. Press \[Enter\] or click within the text field to start the body of the note. Close the Notes dialog by clicking the X button at the top-right corner of the dialog.

Note Number—Indicates which note key you are working with. Click the left arrow to move back to the previous note or the right arrow to move forward to the next note.

Time—Sets the time position for the note key. Change the value to move the note to a new time.

Lock Key—Locks the key to the Time field. When set, the key ignores all operations performed with Move, Slide, and Scale. The only way to change the key's time is to use the Time field in the Notes dialog.

Interface

Add Note Track—Inserts a note track directly below the highlighted items in the Hierarchy list. This is available from the Tracks menu or from the Tools: Track View toolbar.

Notes dialog

Adds or edits notes on the animation in Track View. The first line of your note appears as a label to the right of the note key. You should type a short one- or two-word description as the first line of your note. Press \[Enter\] to start the body of the note. Press \[Enter\] or click within the text field to start the body of the note. Close the Notes dialog by clicking the X button at the top-right corner of the dialog.

Remove Note Track

Use Remove Note Track to delete a note track and its associated keys.

You can have toolbar access to Remove Note Track by unhiding the Tools: Track View toolbar. This toolbar is available only in the Curve Editor, however. The tooltip is labeled Delete Note Track.
Chapter 12: Animation

Procedure

To delete a note track from items:
1. Highlight one or more note tracks in the Hierarchy list.
2. From the Tracks menu, choose Note Track > Remove.

Editing Keys

Topics in this section relate to editing animation keys in Track View. The topics are:
- Edit Keys (page 2–554)
- Snap Frames (page 2–554)
- Lock Selection (page 2–555)
- Align to Cursor (page 2–556)
- Add Visibility Track (page 2–556)
- Move Keys (Dope Sheet) (page 2–558)
- Slide Keys (page 2–558)
- Scale Keys - Time (page 2–559)
- Add Keys (Dope Sheet) (page 2–560)
- Properties (Track View Key Window) (page 2–560)

Edit Keys

Edit Keys displays your animation as a series of keys as boxes on a grid in the Key window. Dope Sheet Editor turns on Edit Keys by default.

Edit Keys is useful for getting a global view of your animation because it displays animation timing for all tracks. Use this mode for key and range editing when you want to view your changes in the context of the total animation.

Use Edit Keys mode to:
- Select and change one or more keys
- Drag range bars to change all animation in multiple tracks

Procedures

To turn on Edit Keys mode, do one of the following:
- If you are in Curve Editor, choose Modes > Dope Sheet.
- If you are in Dope Sheet > Ranges, click Edit Keys on the Track View toolbar.

To delete keys in Edit Keys mode:
1. Highlight the keys in the Key window.
2. Press DELETE on the keyboard to delete the selected keys.

Snap Frames

With Snap Frames, all key and range bar positions that are changed are forced to absolute frame increments. This includes selection sets of multiple keys. When Snap Frames is on, each key in a selection set will snap to the nearest frame when the selection is moved or scaled. Default=on.

When you use the Time Display format MM:SS:Ticks, which doesn’t use frames, Snap Frames snaps to time values that match frame boundaries.
In Dope Sheet > Edit Keys mode, keys are displayed as a box grid. Keys that are snapped to frames are displayed as filled boxes. Keys that have been moved with snap frames off are displayed as narrow rectangles within the grid. When using the Curve Editor, a similar display is available in the track bar.

**Warning:** Don't turn off Snap Frames unless you have a reason to, such as the need for more precise animation timing. If you do turn off Snap Frames and move keys in Curve Editor you will create sub-frame keys, but they won't be noticeably different in Curve Editor. In some cases, sub-frame keys can lead to animation “popping,” or overly fast changes due to keys being too close together.

### Procedure

#### To use Snap Frames:

Snap Frames is on by default, so the following procedure only applies if you have turned off snap frames previously.

1. On the Track View Dope Sheet toolbar, click Edit Keys.
   
   **Note:** This isn't an absolute necessity, but it makes it easier to see the snapping action. You can also view the snapping in the track bar in either Dope Sheet or Curve Editor mode.

2. On the Track View toolbar, turn on Snap Frames.

3. In the Track View Key window, select one or more keys.

4. Use Move Keys or Scale Keys to move keys.

With Snap Frames on, each key in a selection set snaps to the nearest frame when the selection is moved or scaled.

---

### Lock Selection

- **Track View > Curve Editor or Dope Sheet > Highlight keys**
- **Track View toolbar > Lock Selection**
- **Keyboard > SPACEBAR**

Lock Selection toggles selection locking on and off. When a selection is locked you can’t inadvertently deselect or select anything else. When a selection is locked you don’t have to click it to move the keys, you can click anywhere in the window to move or scale the keys.

**Note:** To use the **Spacebar** keyboard shortcut, the **Keyboard Shortcut Override Toggle (page 3–872)** must be on.

#### Procedure

#### To use Lock Selection in Track View:

1. In either Dope Sheet or Curve Editor Key window, highlight one or more keys.

2. On the Track View toolbar, turn on Lock Selection, and then click and drag inside the Track View Key window.

   All the selected keys move regardless of where inside the Track View Key window you click and drag.
Align to Cursor

In either Dope Sheet or Curve Editor, select keys to align to current frame. > Keys menu > Align to Cursor

Use Align to Cursor to move selected keys to the current time. Select the keys to align using Move, Slide, or Scale.

Align to Cursor is useful for taking a group of scattered keys and moving them to the same time location.

Align to Cursor is available in Dope Sheet and Curve Editor modes.

Align Keys to Cursor ignores the state of Snap Frames, and always uses the exact time set by the time slider.

Procedure

To move all selected keys to the current frame:
1. Open either Curve Editor or Dope Sheet - Edit Keys mode.
2. Drag the time slider to the time where you want the keys aligned.
3. Highlight one or more keys using Move Keys, Slide Keys, or Scale Keys.
4. From the Keys menu choose Align To Cursor.
   The leftmost selected key in each track is moved to the current time. Multiple selected keys on the same track maintain their relative distance from the leftmost key.

Add Visibility Track

Right-click an object in the viewport. > Curve Editor/Dope Sheet > Tracks menu > Visibility Track > Add

Graph Editors menu > Track View - Dope Sheet/Track View - Curve Editor > Click the object whose visibility you want to key. > Tracks menu > Visibility Track > Add

Add Visibility Track controls when you can see an object. Visibility tracks can only be added to objects. You can create a visibility track by either animating the Visibility parameter in the Object Properties dialog or by selecting an object in the Track View Hierarchy and clicking Tracks menu > Visibility Tracks > Add. In both cases a visibility track, using a Bezier float controller, is created in Track View. The visibility track displays as a child of the object in the Track View Hierarchy.

Note: In the Object Properties dialog, Rendering Control must be set to By Object in order to keyframe the Visibility using the spinner.

Note: Right-click over an object in the viewports and select Properties to display the Object Properties dialog.

Warning: An object without mapping coordinates that is invisible at frame 0 will not ask for UVW Map coordinates at render time. The warning will display at the frame that the object becomes visible. This can stop a render midway, so make sure invisible objects at the beginning of your animation have mapping coordinates if necessary.

On and Off Visibility

When you first assign a visibility track to an object, a Bezier float controller is automatically assigned; this allows gradual visibility. You can make an object appear or disappear suddenly by changing the interpolation of the visibility keys to Step tangency.
Variable opacity is supported in the shaded viewports. For ease of use, the object never completely disappears from the viewports.

**Visibility Inheritance**

An object can inherit the visibility of its parent (as determined by the parent’s Visibility track in the Track View). Use the Object Properties > Inherit Visibility check box to specify the visibility inheritance of an object.

**Groups and Visibility**

All members of a Group inherit the visibility of the parent when a visibility controller is assigned to the parent. Transparent materials and hidden objects have no effect on this function.

**Level of Detail Utility and Visibility**

The Level of Detail utility (page 1–1253) lets you construct an object that alters its geometric complexity or level of detail based on its size in the rendered image. You create several versions of the same object each with different levels of detail; you group them as one, and then assign the Level of Detail utility. This automatically creates a special LOD controller as a Visibility track.

**Procedures**

To add a visibility track to objects:

1. In Track View Curve Editor or Dope Sheet Edit Keys mode, highlight the object you want to affect in the Hierarchy list on the controller window.
2. From the Track View > Tracks menu, choose Visibility Tracks > Add.
3. Select the keys then use Controller > Properties to adjust the key values and interpolation.
   A value of 0 creates an invisible object, a value of 1.0 creates a fully visible object. Change the interpolation to step for sudden visibility, rather than gradual fades.

A visibility track appears below the selected object(s). Add and edit keys in the visibility track to control the object’s visibility.

To add visibility keys:

1. Once you have a visibility track assigned to the object, highlight the track.
2. On the toolbar, click Add Keys.
3. On the Track View Key window, click in a visibility track to add a key at that time location.

**Example: To create and animate a visibility track using the Object Properties dialog:**

1. Create a box.
2. Turn on Auto Key.
3. Move the time slider to frame 10.
   This is the frame at which you’ll set the box to disappear.
4. Right-click the object and choose Properties from the shortcut menu.
5. In the General tab, set Visibility to 0, and then click OK.
6. Scrub the time slider.
   The box fades. This creates a visibility track in Track View and adds a key with a value of 0 to the track.
Move Keys (Dope Sheet)

Move Keys lets you reposition keys horizontally, within their own track(s), thus changing the times at which they take effect. If no keys are highlighted, you can move any key by dragging it. If multiple keys are highlighted, you can move them all the same distance by dragging one of them.

You can clone highlighted keys by moving them while holding down the Shift key.

Note: You can use any button on the Move Keys flyout to move keys in Dope Sheet mode, but you can move keys horizontally only.

Procedure

To move a selection of keys:

1. On the Keys: Dope Sheet toolbar, click Move Keys if it isn’t already highlighted. It should be on by default.
2. Highlight the keys you want to move in the Key window by dragging a selection rectangle around the keys. You can also use Ctrl+click to highlight non-contiguous keys.
3. Position the mouse cursor over one of the highlighted keys, and then drag horizontally to move the keys in time.

Tip: Press SPACEBAR to lock the key selection. Then you don’t have to drag over the selected key, but anywhere in the viewport. This is useful when you have a complex selection set of keys.

Slide Keys

Use Slide Keys to move a group of keys (highlighted keys plus all the keys to one end of the animation). The direction that you drag determines which group of keys moves:

- Dragging to the right moves the highlighted keys, plus all keys to the last key of the animation, forward in time.
- Dragging to the left moves the highlighted keys, plus all keys to the first key of the animation, backward in time.

Slide Keys is a way to split the animation at the highlighted keys and spread the ends apart. Slide Keys is available in Edit Keys mode.

You can clone keys and insert them elsewhere in your animation curve while offsetting existing keys by the length of time occupied by the cloned keys by dragging while holding down Shift. Based on the length of your selection, the existing keys to the right of the selection move forward in time (that is, to the right) to allow the new key insertion, whether you drag to the right or the left.

Procedure

To slide a selection of keys:

1. Click Slide Keys on the Track View toolbar.
2. Highlight one or more keys.
3. Drag to slide the keys to the right.
   The keys following your selection move to account for the offset produced by sliding the keys.

4. Highlight another group of keys.

5. Hold \textbf{Shift} while dragging to slide the keys to the right.
   The keys following your selection move to the right by the length of time occupied by the cloned keys.

### Procedure

To use Scale Keys:

1. Select an animated object in the viewport, then right-click and choose Curve Editor.
   The following steps work in either Curve Editor or Dope Sheet modes.

2. Drag the time slider to the time you want to use as the scale center.

3. Click Scale Keys or from the Keys menu choose Scale Keys - Time.

4. Highlight one or more keys.

5. Drag to scale the selected keys or press and hold \textbf{Shift} and drag to add scaled copies of the selected keys.
   Drag away from or toward the current time line for the following results:
   - Dragging away expands the keys from the current time. Expanding the selection increases time between the selected keys and slows that part of the animation.
   - Dragging toward shrinks the keys toward the current time. Shrinking the selection reduces time between the selected keys and accelerates that part of the animation.
   - Dragging through the current time reverses the keys and expands the keys away from the current time.

Tip: You can type-in the Scale Value using the first field in the Key Stats: Track View toolbar.

The scale percentage is displayed in the Show Selected Key Stats field as you drag the selection.
Add Keys (Dope Sheet)

Add Keys inserts a key (page 3–960) at the point where you click a curve or a track.

Add Keys is a mode that remains active until you activate another mode. While Add Keys is on, you click in any animation track to add a key at that location in time.

Procedure

To add keys in Track View:

1. On the Track View toolbar, click Add Keys.
2. Click an animation track to add a key.
   
   The location where you click sets the time of the key as measured on the time ruler.

   The value of the new key is set by one of the following conditions:
   
   • Keys added before the first key of a track receive the same value as the former first key.
   • Keys added between two keys receive an interpolated value based on the values of the original keys.
   • Keys added after the last key in the track receive the same value as the former last key.

   If you are unable to add keys to a track, check the following conditions:
   
   • Only animated tracks can accept keys. If you want to add a key to a track, such as an object parameter, you need to animate it first.
   • The animation controller must be a type that uses keys. Not all controllers use keys.

   Examples of controllers that do not use keys include procedural controllers such as Noise.

   • The animation controller must be a type that uses keys. Not all controllers use keys. Examples of controllers that do not use keys include Expression controllers, List controllers, and Parametric controllers.

Properties (Track View Key Window)

Properties displays a dialog to change animation values. The type of dialog displayed depends on the type of animation controller the selected track is using. The Properties function is unavailable if the selected track controller does not use properties, or the track selection set is incorrect.

• A track with animation keys display a Key Info dialog (page 2–304). You can change the values in the Key Info fields to change the animation value, time, and interpolation methods of one or more selected keys.

• A track with a parametric controller, such as Noise (page 2–353), displays a Properties dialog. You change the values in the Properties dialog to modify the behavior of the controller over its entire range.

Access the Properties dialog through the controllers quad of the right-click menu, or on the Controller menu > Properties. The same dialog is also accessible through the Motion panel.

You can also display the Key Info dialog by right-clicking a key in the Key window. Parametric
controller dialogs can also be displayed by right-clicking their range bars.

The Properties button is unavailable in ambiguous cases, for example, when a key and a Parametric controller item are both selected.

Procedures

To display properties for a controller, do one of the following:

- Highlight the track and then choose Controller menu > Properties.
- Right-click the track, and then on the Controllers quad choose Properties.

To display the Key Info dialog for a key:

1. Right-click the key in the Curve Editor Key Window.
2. Change key properties in the dialog.

Track View Utilities

Track View Utilities displays a dialog listing plug-in Track View utilities. A typical Track View utility displays a modeless dialog (though utilities can be modal) and provides functions that can be applied across multiple selected keys and tracks. You can launch more than one utility by choosing Track View Utilities again.

Available Utilities

- Randomize Keys (page 2–562): Applies random offset values to Time or Value of selected keys or selected time.
- Create Out of Range Keys (page 2–562): Creates keys in the out-of-range time of a track, when the Out of Range type is something other than Constant. Thus, it converts the specified out-of-range area to a keyed area that you can edit and adjust. Select one or more tracks, set the parameters of the utility, and click Apply. In Function Curve display mode, you must select the curve as well as the track.
- Select Keys by Time (page 2–563): Selects keys within a specified start and end range of time. Lets you select a large range of time when using the mouse might be awkward—for example, if keys are not visible in the Track View Key window.
- Euler Filter (page 2–564): Displays a dialog with controls to remove gimbal flipping from animated tracks using Euler rotation.
- Soft Selection Settings Manager (page 2–525): Displays a dialog with controls to adjust the range and falloff of the soft selection of keys in the Dope Sheet and Curve Editor.
- Current Value Editor (page 2–565): Provides transform type-in capability from within the Track View modes. Allows you to choose between absolute and relative value editing. The name of the controller appears above the axis choices. This utility launches a floating Current Value window that works for either Dope Sheet — Edit keys mode or Curve Editor. It doesn’t work for Edit Ranges.

Procedure

To select a Track View utility:

1. Open Curve Editor, and then from the Utilities menu, choose Track View Utilities.
2. In the Track View Utilities dialog, choose from the available utilities, and click OK.
Randomize Keys Utility

Track View > Utilities menu > Track View Utilities > Randomize Keys

Randomize Keys applies random offset values to the times and/or values of selected keys.

Procedure
To use Randomize Keys:
1. Highlight one or more keys, or a block of time, in one or more tracks.
   In Dope Sheet > Edit Keys mode, all selected keys are affected. In Edit Ranges mode, the keys in the selected tracks that are within the selected range of time are affected. In Curve Editor mode, the selected keys on selected curves are affected.
2. From the Utilities menu, choose Track View Utilities, and then choose Randomize Keys.
   The Randomize Keys utility is displayed.
3. By default, both Randomize Time and Randomize Value are on. Turn off either if you wish.
4. Set the +/- spinners to specify the desired range of randomized offset.
5. Click Apply.

Interface

| Randomize Keys | Randomize Time—Randomly shifts values in time, based on the spinner settings. For example, if the + spinner is set to 20, and the - spinner is set to 10, the values could shift up as much as 20, and down as much as 10.
| Randomize Value—Randomly shifts values, based on the spinner settings.
| Randomize group box—You can apply randomization either with selected keys or with selected time. When applying to selected keys, this displays the message: "All selected keys." However, when you select a block of time in Edit Time mode (page 2–566), this message is displayed: "Keys in selected tracks that are in the range: n to n."
| Apply—Applies the specified random offset values to the selection. You can click this repeatedly for more randomization.

Create Out of Range Keys Utility

Track View > Utilities menu > Track View Utilities > Create Out of Range Keys

Create Out of Range Keys creates keys in the out-of-range time of a track when the out of range type is something other than Constant. It converts the specified out-of-range area to a keyed area that you can edit and adjust.

This utility works both in Curve Editor and Dope Sheet modes.
In Curve Editor mode, you must select the curve as well as the track.

Procedure

To use Create Out of Range Keys:

1. In the Track View Controller window, select the Position track of an animated object.

2. On the Track View toolbar, click Parameter Curve Out-of-Range Types button to apply an out-of-range type curve to the selected track.

   Use any curve type except Constant (the default).

3. Click Utilities menu > Track View Utilities. In the dialog box that appears choose Create Out of Range Keys.

4. Set the desired parameters in the Create Out of Range Keys dialog.

5. Click Apply.

   Keys are created in the out-of-range areas of the position track. The track bar expands to the boundaries of the newly created keys.

Interface

Time Range group

Sets the time after the range for generating keys. For example, if your range of keyed animation is from frame 31 to 54, the out-of-range animation might be from 0 to 30 and from 55 to 100.

- **Before**—Specifies the number of frames before the range for generating keys. In the previous example, if you set this option to 20, it would generate keys over frames 10 to 30. When you set this option to 0, no keys are generated before the range.

- **After**—Specifies the number of frames after the range for generating keys. In the first example, if you set this option to 40, it would generate keys over frames 55 to 95. When you set this option to 0, no keys are generated after the range.

- **Samples**—Specifies the number of keys to be generated for both the before and after time range, based on the settings in Before and After. In the example above, if Samples is set to 20, 20 new keys would be generated over frames 10 to 30, and another 20 new keys would be generated over frames 55 to 95.

- **Apply**—Generates the keys.

   Note: Keys are generated only for non-constant out-of-range types. If the area before or after the range is the default, Constant type, no keys are generated in that area.

Select Keys By Time Utility

The Select Keys By Time utility lets you select keys within a specified start and end range of time. You can select a large range of time, which might be difficult to select using the mouse in the Track View Key window for example.

This utility works in Curve Editor and Dope Sheet Edit Keys modes.
Procedure

To use Select Keys By Time:

1. In the Controller window, highlight the tracks you want to work with.

2. On the Utilities menu choose >Track View Utilities, then choose the Select Keys By Time utility from the Track View Utilities dialog.

3. Set a range and click OK.
   - Keys within the range in the highlighted tracks are selected.
   - If you select Clear Previous Selection, all keys are cleared before the keys within the time range are selected.
   - In Dope Sheet, highlight a single track to select all keys in the descendants of the track.

Interface

Start Time—Specifies the start range for selecting keys.

End Time—Specifies the end range for selecting keys.

The Start Time and End Time spinners are activated to match the current time selection.

Clear Previous Selection—Clears all keys before keys within the specified time range are selected.

In Dope Sheet mode, highlight a single track to select all keys in the descendants of the track.

Modify Subtree must be on for this to work.

Euler Filter

This Track View utility corrects for gimbal flipping (anomalous rotation animation) in objects animated using Euler rotation (page 2–318) by processing existing animation keys in selected animated tracks. It’s particularly useful for cleaning up rotation artifacts when importing raw motion-capture data. This process does not break any keyed orientations.

By default, the utility modifies only frames with keys on all three tracks (X, Y, and Z). By turning on Add Keys If Needed, you can perform the correction on frames with X, Y, and Z keys and also add keys at frames that contain only one or two keyed axes but require correction, resulting in X, Y, and Z keys at those frames.

The default range for filtering is the current active range for the scene, which automatically appears in the utility. To isolate the operation to a specific subset of the animation, change the Start Time and End Time settings. Any changes made to the utility remain active during the current 3ds Max session.

Tip: The utility works in Dope Sheet mode, but it’s much easier to see what it’s doing if you use Curve Editor mode.

Procedure

To use Euler Filter:

1. Select an object animated with Euler rotation (page 2–318).

2. Right-click the object, and from the quad menu choose Curve Editor.

   Track View opens in Curve Editor mode, with the animated tracks highlighted.

3. Make sure the rotation tracks to be filtered are highlighted in Track View.
4. From the Utilities menu in Track View, choose Track View Utilities.
   This opens the Track View Utilities dialog.
5. In the list of utilities, click Euler Filter and then click OK, or just double-click Euler Filter.
   This opens the Filter Selected Euler Tracks dialog.
6. Change the parameters as necessary, and then click OK.
   The utility adjusts the rotation keys to removed gimbal flipping.

**Interface**

**Start/End Time**—The range over which the filtering should occur. Default=current animation range.

**Add Keys If Needed**—When on, the utility performs the correction on frames with X, Y, and Z keys and also adds keys at frames that contain only one or two keyed axes but require correction, resulting in X, Y, and Z keys at those frames.

**OK**—Performs the filtering using the current settings.

**Cancel**—Closes the dialog without performing the filtering.

---

### Absolute and relative value editing

Absolute and relative value editing let you increment changes, or apply exact values. The name of the controller whose values are being changed appears above the axis choices.

This utility opens a dockable Current Value window that works for either Dope Sheet - Edit keys mode or Curve Editor. It doesn’t work for Edit Ranges.

**Procedure**

**To use the Current Value Editor to apply an incremental change:**

1. Select the position track of an animated object.
2. Choose Utilities > Track View Utilities > Current Value Editor.
3. Turn on Relative.
4. Change the values for X, Y, or Z.
   The numbers you enter add a relative increment to the existing values.

**Interface**

**Absolute**—Applies world space values to the keys. The numbers you enter are the numbers that are applied.

**Relative**—Increments the values relative to their existing value. The numbers you enter are added to the existing value.

**Controller type**—Displays the name of the controller about the X, Y, and Z fields.
X, Y, Z—Use these fields to input numbers for relative or absolute value editing.

### Edit Time

Use the Edit Time tools to work directly with selected blocks of time in the Dope Sheet Editor, as opposed to working with keys and range bars. A block of time is any contiguous time segment, across one or more tracks, and is independent of key locations.

Enter Edit Time mode by selecting a time segment in the Dope Sheet Editor. Once a time segment has been selected you can insert, cut, copy, paste, or reverse the time segment, including its keys. The time tools are available from the Time menu and the Time: Dope Sheet toolbar. Time tools are unavailable from the Time menu in Edit Ranges mode.

In Edit Time mode, keys and range bars of your animation are there only for reference. You select blocks of time and then apply time-editing functions to your selection.

### Edit Time Mode Controls

In Edit Time mode you can perform the following tasks for one or more tracks:

- **Select Time** (page 2–566)
- **Delete Time** (page 2–567)
- **Cut Time** (page 2–567), **Copy Time** (page 2–568), **Paste Time** (page 2–568)
- **Reverse Time** (page 2–569)
- **Insert Time** (page 2–570)
- **Scale Time** (page 2–570)
- **Exclude Left End Point** (page 2–570)
- **Exclude Right End Point** (page 2–571)
- **Reduce Keys** (page 2–572)

### Procedure

**To edit time:**

1. Select the animated object in the viewport, then right-click and choose Curve Editor. This opens Track View navigated to the animated object.
2. On the Modes menu choose Dope Sheet mode. The Key window changes from curves to a key spreadsheet.
3. If Edit Keys isn't highlighted on the Keys: Dope Sheet toolbar, click it to turn it on. The next steps won't work if you have Edit Ranges on instead of Edit Keys.
4. From the Time menu, choose Select Time.
5. Expand and activate the tracks you wish to alter. For example you could select the Z Position transform track of a bouncing Box object.
6. Drag a time segment out in the Key window. A tooltip displays the selected Start and End frame numbers interactively as you drag. This selects the time segment including any keys within it.
7. Perform any of the time tool operations available from the Time Menu or the Time: Dope Sheet toolbar.

### Select Time

With Select Time you can specify a block of time by dragging in the Key window. You can then apply
any of the following operations to the highlighted block (and any keys contained therein):

- **Delete Time** (page 2–567)
- **Cut Time** (page 2–567)
- **Copy Time** (page 2–568)
- **Paste Time** (page 2–568)
- **Reverse Time** (page 2–569)
- **Insert Time** (page 2–570)
- **Scale Time** (page 2–570)
- **Exclude Left End Point** (page 2–570)
- **Exclude Right End Point** (page 2–571)
- **Reduce Keys** (page 2–572)

**Procedure**

**To select time:**

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. **On the toolbar, click the Select Time button.**

3. Drag in the keys window to specify time in the selected tracks.

   A beige bar between two yellow lines appears as you drag across the box grid of the Dope Sheet Key window.

   If a highlighted track does not support time operations, time selection in that track is ignored.

   After specifying a time range, you can perform other time- and key- related operations.

---

**Delete Time**

![Delete Time](image)

Track View > Dope Sheet > Specify a time block. > Time: Dope Sheet toolbar > Delete Time button

Use Delete Time to delete a selected block of time and any keys inside the selected block. Keys to the right of the deleted time move to the left.

**Note:** The deleted block is not copied to the clipboard.

**Procedure**

**To delete a block of time:**

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. **Use Select Time** (page 2–566) to specify a block of time.

3. **Click Delete Time.**

   Keys in the specified time block are deleted, and any keys to the right of the block move leftward.

---

**Cut Time**

![Cut Time](image)

Track View > Dope Sheet > Specify a time block. > Time menu > Cut

Track View > Dope Sheet > Specify a time block. > Time: Dope Sheet toolbar > Cut Time button

Use Cut Time to delete a block of time from one or more tracks and place it in the clipboard. Before you can paste time in a track, you must have time in the clipboard. After specifying a block of time, place it in the clipboard with Cut Time or **Copy Time** (page 2–568).
Procedure

To cut time from tracks:

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. Use Select Time (page 2–566) to specify a block of time.

3. Click Cut Time, or, from the Time menu, choose Cut Time.
   The block of time is deleted from the selected tracks and stored in the time clipboard. Keys to the right of the deleted time move left.

Copy Time

Use Copy Time to copy a block of time from one or more tracks to the clipboard, after which you can paste it to other tracks.

You can use the clipboard to copy time, with keys, to different places in the same track or from one track to another. For example, you can copy position keys from one object to another.

Procedure

To copy time from tracks:

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. Use Select Time (page 2–566) to specify a block of time.

3. Click Copy Time, or choose Time menu > Copy.
   The block of time is copied to the time clipboard. The original block remains unchanged.

Paste Time

Use Paste Time to paste a block of time from the clipboard into one or more tracks.

The conditions for pasting time into a track are:

- If the block of time on the clipboard is from a single track, you can paste it into any track using the same type of controller.
- If the block of time on the clipboard is from multiple tracks, you can paste it into a selection of multiple tracks as long as the controllers for the selected tracks include valid track types. For example, position tracks in the clipboard are pasted to position tracks in the selection.

If the above conditions are not met, the Paste Time function has no effect.

Time editing is available only in Dope Sheet mode; it is not available in the Function Curve Editor.

In Edit Time mode, you can copy and paste controller tracks that have no animation keys. When a track has no key, its value at frame 0 is used. You must select a block of time before cutting or pasting; otherwise the time is ignored.
Relative and Absolute Pasting

The values of all the pasted keys are adjusted so that the first pasted key has a value equal to the value at the time of the insertion point. For example, the value of the controller at frame 50 is 10. The clipboard holds three keys spanning 50 frames with values 20, 30, and 40. When you paste the three keys at frame 50, the first key has a value of 20, but the insertion point has a value of 10. 3ds Max subtracts 10 from the pasted key to maintain the value at the insertion point. 3ds Max then subtracts 10 from the remaining pasted keys, resulting in three pasted keys valued at 10, 20, and 30. In addition, any keys after the insertion range are also adjusted by the net change over the range being pasted. The net change is the value of the last key pasted minus the value of the first key pasted. In this case 40-20=20. Every key after the insertion point is increased by 20.

Procedure

To paste time into tracks:

1. In Dope Sheet mode, after using Cut Time (page 2–567) or Copy Time (page 2–568), highlight one or more item labels in the Controller window to specify tracks for pasting.

2. Use Select Time (page 2–566) to specify a block of time.

3. Click the Paste Time button on the Time: Track View toolbar.

   The Paste Track dialog opens.

4. In the Paste Track dialog, choose Paste Absolute or Paste Relative, and then click OK.

Interface

Options on the Paste Track dialog are as follows:

Paste Absolute—Replaces the current animation values with the values in the clipboard. Use this method when you want to replace one animated effect with another.

Paste Relative—Adds the animation values in the clipboard to the current animation values. Use this method when you want to layer animation onto an existing effect.

Reverse Time

Reverse Time flips the order of keys within the selected time. You can reverse time by scaling a selection past its left edge, but this also changes the position of the selection and the remaining keys around it. Use Reverse Time to reverse keys within a designated block of time.

Procedure

To reverse time:

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. Use Select Time (page 2–566) to specify a block of time.
3. Click the Reverse Time button, or choose Time menu > Reverse.

The position of the selected block of time does not change, but order of keys within the block is reversed.

**Insert Time**

**Procedure**

**To insert time into tracks**

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. On the Dope Sheet toolbar, click the Insert Time button.

3. Drag in the Key window to insert time into the tracks.

**Tip:** To insert time globally, highlight the World track, turn on the Modify Child Keys button, then insert time into the World track.

**Scale Time**

**Procedure**

**To scale time:**

1. In the Dope Sheet Editor, on the Time: Dope Sheet toolbar, click Scale Time.

2. In the controller window, click item labels to highlight tracks for time editing.

3. Drag out a time block in the Key window, or use an existing block.

4. Move your cursor over the active time block in the Key window. The cursor changes to show you when you can scale.

5. Do one of the following:

   - Drag to the right within the selection to expand time from the left edge of the selection. All keys to the right of the selection slide right as the selection expands.

   - Drag to the left within the selection to reduce time towards the left edge of the selection. All keys to the right of the selection slide left as the selection shrinks.

   - Drag past the left edge of the selection to reverse time and expand it with a negative scale factor. Keys inside the selection, and keys to the right of the selection, can overlap keys to the left of the selection.

**Exclude Left End Point**

**Procedure**

Use Exclude Left End Point to exclude the beginning key in a selected block of time.

If you paste the same block of time repeatedly, one block following the other, you can create a looping
segment in your animation. To create a smooth looping animation, you need to exclude either the first or last key of the copied block to prevent keys from doubling up at the ends.

The key to be excluded must be at the exact start time of the copied block of time.

Note: By default, the Extras: Dope Sheet toolbar doesn’t appear in the Dope Sheet Editor. You’ll find a method for displaying it in the following procedure.

Procedure

To animate a loop by copying and pasting keys:

1. In Dope Sheet mode, highlight one or more item labels in the Controller window to specify tracks for time editing.

2. Use Select Time (page 2–566) to specify a block of time.
   At least one track in the block should start with a keyframe. Also, for a smooth loop, the first and last frame of the selection should be the same.

3. Right-click an empty section of the toolbar area and choose Show Toolbars > Extras: Dope Sheet.
   The Exclude Left End Point and Exclude Right End Point buttons appear.

4. On the Track View toolbar, click Exclude Left End Point.

5. On the Track View toolbar, click Copy Time.
   The selection is copied to the clipboard, minus the first frame.

6. Click to define an insertion point in the keys window.

7. Click Paste Time.
   The Paste Time dialog appears.

8. In the dialog choose Paste Absolute or Paste Relative. For an animated loop choose Paste Absolute, then click OK.
   The time, including keys, is pasted.

9. Play your animation to observe the effect.
At least one track in the block should end with a keyframe. Also, for a smooth loop, the first and last frame of the selection should be the same.

3. Right-click an empty section of the toolbar area and choose Show Toolbars > Extras: Dope Sheet.
The Exclude Left End Point and Exclude Right End Point buttons appear.

4. On the Track View toolbar, click Exclude Right End Point.

5. On the Track View toolbar, click Copy Time.
The selection is copied to the clipboard, minus the first frame.

6. Click to define an insertion point in the keys window.
The last position key should be your insert point.

7. Click Paste Time.
The Paste Time dialog appears.

8. In the dialog choose Paste Absolute or Paste Relative. For an animated loop choose Paste Absolute, then click OK.
The time, including keys, is pasted.

9. Play your animation to observe the effect.

Reduce Keys

Use Reduce Keys to decrease key density. Animating with inverse kinematics, or creating any complex animation, can result in many keys, which can make editing the animation difficult. In the case of applied inverse kinematics, the software generates a key on nearly every frame. Often, the same animation can be produced with fewer keys. Having fewer keys in a track makes it easier to change your animation.

Reduce Keys analyzes the pattern of keys in a block of time and creates a new pattern of fewer keys that produces nearly the same animation. You specify how closely the new animation matches the original.

Note: The Reduce Keys button, depicted above, appears on the Keys toolbar only in Curve Editor, but you can add it to a Dope Sheet toolbar with Customize User Interface (page 3–792).

Procedure

To reduce keys:

1. Select an animated object in the viewport.

2. Right-click the object and choose Curve Editor or Dope Sheet from the quad menu.

3. In the Hierarchy list, highlight the tracks whose keys you want to reduce. Reduce Keys works only on highlighted tracks.

4. Optionally, in the Key window, specify a time range within which to reduce keys. Highlight a key at either end of the range to reduce, or drag a selection rectangle around the keys you want to reduce.
want to reduce. Alternatively, in Dope Sheet mode, highlight specific tracks and then use Select Time (page 2–566) to designate a block of time within which to reduce keys. If no keys are highlighted in a highlighted track, Reduce Keys works on all keys in that track.

You can use any of the above methods to specify different ranges for different highlighted tracks.

5. From the Keys menu, choose Reduce Keys.

The Reduce Keys dialog appears. This dialog has a single Threshold parameter.

Raising the Threshold setting will increase the number of keys that are reduced. The higher the threshold, the greater the reduction.

6. Click OK to reduce the keys.

Observe the results. If you are left with too few keys, press Ctrl+Z to undo, then lower the threshold and reduce the keys again. If too many keys remain, increase the threshold and reduce keys again.

Tip: It will take repeated experimentation to find exactly the right threshold for your particular animation.

**Interface**

![Reduce Keys dialog]

*Reduce Keys*—Displays the Reduce Keys dialog.

*Threshold*—Sets a threshold value. Higher values will result in fewer keys.

*OK*—Accepts the Threshold setting and reduces keys as follows:

- Keys are reduced only in highlighted tracks.

- If any of a track’s keys are highlighted, reduction is performed only within the indicated range (that is, between the leftmost and rightmost highlighted key for each track). If no key is highlighted, reduction is performed on all keys in the track.

**Edit Ranges**

![Edit Ranges dialog]

Edit Ranges displays all tracks as range bars. This mode is useful for quickly scaling and sliding complete animation tracks.

- Drag the range bar of an animation track to change all animation in that track.

- Drag range bars in higher-level tracks to change all animation in multiple tracks.

Note: You cannot access individual key values in this mode.

The Ranges: Dope Sheet toolbar contains tools for working with Ranges. Right-click an empty area adjacent to the Dope Sheet toolbar and choose Show Toolbars > Ranges: Dope Sheet to display the toolbar. Save your layout after you do.

Besides the Edit Ranges button, the Ranges: Dope Sheet toolbar shows the following buttons:

*Position Ranges* (page 2–574)

*Recouple Ranges* (page 2–574)

**Procedure**

To drag the ranges of an object and all of its linked descendants:

1. On the Track View toolbar, click Edit Ranges.
Chapter 12: Animation

2. On the Track View toolbar, click Modify Subtree.

3. In the Track View Key window, drag an Object range bar or the World range bar.

   With Modify Subtree on, a range bar displays in the Objects track. The Objects branch is the default parent of all objects in the scene.

   Dragging a parent-object range bar with Modify Subtree on affects all tracks subordinate to the object and all tracks of all of its linked descendants.

### Position Ranges

Position Ranges mode allows you to position range bars independently from their associated keys and produce special effects.

The process of adjusting a range bar independent of its keys is called *decoupling the range*. Positioning a range bar so it matches the first to last keys of a track is called *recoupling the range*.

**Note:** The Ranges: Dope Sheet toolbar doesn’t appear in Track View by default. To open it, right-click an empty area adjacent to the Dope Sheet toolbar and choose Show Toolbars > Ranges: Dope Sheet. Save your layout after you do.

#### Decouple a Range Bar

You decouple a range bar for two reasons:

- You want some keys at the start or end of an animation range not to take effect.

  Keys outside of the range bar are ignored during animation playback. The keys outside the range still affect interpolated values inside the range, but the applied Out-of-Range type is used to animate time outside the range bar.

- You want to add extra time before the first key or after the last key that is not affected by the applied Out-of-Range type.

  Time beyond the first or last key of the track, but still within the range, uses the constant value of the nearest key within the range.

**Procedure**

**To decouple a range bar from its keys:**

1. Right-click an empty area adjacent to the Dope Sheet toolbar and choose Show Toolbars > Ranges: Dope Sheet.

2. On the Track View toolbar, click Position Ranges.

3. In the Track View Key window, drag the entire range bar left or right of the keys, or drag either end of the range bar to make it longer or shorter than the keys.

   Using *Out-of-Range types (page 2–551)* in conjunction with this procedure allows you to change the behavior of an animated loop. Positioning either end of a range bar changes the loop.

### Recouple Ranges

Recouple Ranges resizes the range bar so that the beginning and end of the range matches the first and last keys in the track. This is useful to quickly realign the range and the keys after editing.

**Note:** The Ranges: Dope Sheet toolbar doesn’t appear in Track View by default. To open it, right-click an empty area adjacent to the Dope
Sheet toolbar and choose Show Toolbars > Ranges: Dope Sheet. Save your layout after you do.

Procedure
To recouple a range:

1. Right-click an empty area adjacent to the Dope Sheet toolbar and choose Show Toolbars > Ranges: Dope Sheet.

2. On the Track View toolbar, click Position Ranges.

3. Select one or more item labels in the Hierarchy list to select tracks to be recoupled.

4. On the Track View toolbar, click Recouple Ranges.

The range bars for the selected tracks are positioned to match up with the first and last keys in their track.

Position Ranges mode allows you to decouple the range bar from the animation keys. Recouple Ranges is a quick way to realign the range bars.

---

Editing Tracks: Copying, Pasting, and Handling Instances and References

Copying and Pasting Items
You can copy and paste geometry, lights, materials, and animation controllers between items in the Track View Hierarchy list of the controller window. You can copy these categories of items in Track View:

Containers—Items with multiple branches that completely define something in your scene. Container items that can be copied include:

- Material Parameters containing the Basic Parameters for a material definition.
- Material Maps containing the entire set of maps and map parameters assigned to a material.
- Map definitions containing a single map type with its associated parameters and coordinates.
- Map Coordinates containing the map XYZ and UVW coordinate offset, tiling, and angle settings.
- Map Parameters containing the parameters for a specific map type.
- Objects, on levels below the transforms, containing creation parameters for an unmodified object.
- Modified Object, containing modifiers applied to an object and the object-creation parameters.
- Modifiers containing modifier parameters.

Controllers—These control actual animated values for each parameter. Keep in mind that when you copy containers, you are actually copying and pasting groups of related controllers. Details about copying and pasting single controllers are presented in Assigning Controllers (page 2–292).

Whether you copy objects, materials, or controllers, the same basic principles apply. Here are restrictions for using Copy and Paste:

- You can copy only a single highlighted item.
- You can paste a copied item only into another item of the same type. An exception to this restriction involves pasting Object and Modified Object containers.
- You can paste a copied item into a selection of multiple items only if all the items are of the same type.
• When pasting items, you can choose to make an instance or a copy of the pasted item.
• You cannot copy/paste actively linked objects.

Copying Items
You copy an item by highlighting it in the Controller window Hierarchy list, and then right-clicking and choosing Copy from the quad menu. If Copy is not available the selected item is not a valid copy source. 3ds Max disables Copy when the selected item is not a valid copy source or if multiple items are selected.

Pasting Items
Pasting items involves a few more choices than copying. You select one or more items from the Hierarchy list. If Paste is available the selected items are valid paste targets. The program disables Paste if the selected targets are not all the same type or if they do not match the type of item in the clipboard.

You can use Paste as follows:
• Paste into a single target item.
• Paste into multiple target items.
• Paste copies or instances.
• Choose to convert other instances in the scene automatically.

Clicking Paste on the quad menu displays the Paste dialog, with controls for determining how the Paste operation will be carried out.

Copy—Pastes the item in the clipboard as an independent copy. The target item will have no connection to the copied source item.

Instance—Pastes the item in the clipboard as an instance of the copied source item. The target item will be an instance of the source item. Any change you make to either item affects the other.

Replace All Instances—Controls whether existing instances of the target item are also converted to the paste source or left as they are.

Making Instances Unique
You can convert instanced items to unique items by clicking Make Unique (page 2–550) on the Controller menu. If the selected item is not an instance, or if a selection of multiple items does not contain similar instances, Make Unique is disabled.

Copying and Pasting Objects
In the Track View controller window you can use the Hierarchy list to copy and paste objects. This allows you to replace the geometry of one animated object with the geometry of another object. This is similar to the functionality provided by XRef objects and scenes where you have to option of defining proxy or stand-in objects.

Copying and pasting objects is achieved by highlighting the Object track for the source object, copying it, then pasting it to the Object track of the target object. The Object track is found beneath the Transforms and Modified objects entries, and appears with parentheses that define the geometry type. For example, Object (Box) or Object (Editable Mesh) are two label names that might appear on the correct track for object cut and paste.

Using these two container types, you can copy geometry between objects.

To copy one object to other objects:
1. In the Curve Editor controller window, find the object that you want to copy from.
2. Navigate to the Object track that is beneath the Transform or Modified Object entries. The name will be something like Object
Making Instance and Reference Controllers and Objects Unique

(PivotDoor) or Object (Editable Mesh), for example.

Note: If the object is modified, the order of the name of its Object track in the Hierarchy list is reversed; for example, Object (Sphere) becomes Sphere (Object).

3. Highlight the object track you wish to copy, then right-click and choose Copy from the quad menu.

4. Navigate to the object track for the target object, highlight it, and then right-click and choose Paste. Set options in the Paste dialog, then click OK.

The object is replaced with the new one in the viewport as well as in the Hierarchy list of the controller window.

**Warning:** The original target has been completely replaced by the pasted object. Use Save Selected (page 3–392) on the target object to save a copy of that object, if you think you’ll need to use it again sometime.

Here are some examples of how you might use object copy and paste:

- Paste an Object to another Object to replace one simple object with another. For example, you animate the transforms of a box object and want to replace the box with a torus.
- Paste an Object into a Modified Object to replace a complex, modified object with a simple stand-in object. For example, you model a complicated vehicle and you want to replace it with a box while you animate its transforms. Be sure to save the Modified Object to a file (using Save Selected (page 3–392)).
- Paste a Modified Object into another Modified Object to replace one complex modified object with another. For example, you animated a flight of jets and want to replace them with helicopters.
- Paste a Modified Object into an Object to replace simple stand-in objects with complex modified objects. For example, you have animated a box and now want to replace it with a complex model of a jet.

**Copying and Pasting Object Modifiers**

You can also copy and paste modifiers below the Modified Object container. Copy and paste modifiers to do the following:

- Copy modifiers within the modifier stack of a single object.
- Copy modifiers between objects.

Unlike pasting other items, modifiers do not replace the highlighted item when you click Paste. Instead, the pasted modifier is inserted above the selected item.

**Making Instance and Reference Controllers and Objects Unique**

You can convert instanced and referenced objects into unique objects by clicking Make Controller Unique on the Track View toolbar or by choosing Make Unique on the Controller menu. The result of clicking Make Unique depends on how the object was instanced or referenced, and which object container you select in the Hierarchy list.

When you make an instance or reference object, you cause the data flow to branch on its way from the master object to two or more named objects.

- In Track View, these branches usually occur at Modified Object containers and sometimes at the base Object container.
- In Track View, instances and references are displayed in bold face.
• In the modifier stack, these branches display as a horizontal line, called a derived object line.

For descriptions of object data flow and instance objects, see Understanding Object Data Flow (page 1–494).

You can make an object unique by selecting a Modified Object or an Object container and clicking Make Unique on the Track View toolbar. Your result depends on whether or not the data flow branches at the selected container.
• If the data flow does not branch anywhere below the selected container, nothing happens.
• If the data flow does branch at or below the selected container, the data flow above the branch is split from the current data flow as a unique object. The data flow from the selected container to the master object is copied and attached to the new unique object.

Making a Selection of Multiple Instances Unique

If you select multiple objects that are instances of each other, or share instanced modifiers, you can choose how to make them unique. After you click Make Unique, the Make Unique dialog appears, with the question, “Do you want to make the selected items unique with respect to each other?”
• Click Yes to make each object in the selection completely unique.
• Click No to leave the objects in the selection as instances, but to make them unique from other objects not in the selection.

Curve Editor

Main toolbar > Curve Editor (Open) > Highlight animated tracks. > Curves are displayed in Key Window.

Graph Editors > Track View - Curve Editor > Highlight animated tracks. > Curves appear in Key window.

Right-click any animated object. > Curve Editor > Curves appear in Key window.

The Curve Editor displays animation as function curves, charting the controllers’ changes of value over time.

Highlighting a controller label displays keys for that item as vertices on the function curve. You can then highlight keys and change their values.

You can add keys to function curves for tracks that are not yet animated. The curves appear as straight lines. When you add a key to a function curve, a controller is created for that track.

Not all controller types display function curves. For example, a TCB Rotation controller doesn’t display a function curve, while an Euler XYZ rotation controller shows individual curves for X, Y and Z. Some controllers display individual tracks for each axis, while other controllers combine the three axis values into a single curve.

The Track View tools for working with function curves, found on the Curve Editor toolbars (page 2–535) and menus, include the following:
Move Keys (Curve Editor) (page 2–579)
Scale Keys (page 2–580)
Slide Keys (page 2–558)
Scale Values (page 2–581)
Add Keys (Curve Editor) (page 2–581)
Draw Curves (page 2–582)
Reduce Keys (page 2–572)
Show All Tangents (page 2–531)
Show Tangents (page 2–582)
Lock Tangents (page 2–583)
Apply Ease Curve / Apply Multiplier Curve (page 2–584)
Remove Ease/Multiplier Curve (page 2–585)
On/Off (Curves) (page 2–585)
Ease Curve Out-of-Range Types (page 2–585)
Multiplier Curve Out-of-Range Types (page 2–586)
Freeze Non-Selected Curves (page 2–587)

Bezier Tangent Handles

You can use Bezier handles in the Curve Editor to change the shape of the trajectory through a key. To display handles on a key, right-click a key in the Track View Key Window and choose the Custom Tangents option. You can assign the Custom Tangent type only to items using a Bezier controller. This will display tangent handles on the keys that you can manipulate horizontally and vertically.

Procedure

To display function curves:

1. Select an animated object in a viewport.
2. Right-click the active viewport and choose Curve Editor.
   The function curves for the object’s animation are displayed in the Key window of the Function Curve Editor.
3. To display additional curves at the same time, from the Track View menu choose Settings > Manual Navigation.
4. Navigate the controller window until you see the additional tracks, and then hold down the [Ctrl] key and click them.
   The curves for all highlighted tracks are displayed together in the Key window.

Move Keys (Curve Editor)

You can clone keys by holding down [Shift] while dragging. The new keys are added to the existing keys on the curve.

You can also clone keys to replace existing keys by holding down [Shift+Alt] while dragging.

Tip: When you select keys to clone and replace others, you can include the key before the first selected key to preserve the tangent of your first copied key.
Procedure

To move a selection of keys:

1. In the Hierarchy list, highlight one or more tracks.
   
   Only keys in highlighted tracks appear in the Key window.
   
   By default, the Move Keys button is yellow, showing it is already on.

2. In the Track View Key window, highlight one or more keys.

3. Drag the highlighted keys to a new location, or press Shift and drag the highlighted keys to add copies at the new location.

4. Highlight another group of keys.

5. Press Shift+Alt, and drag the highlighted keys towards existing keys to replace them with copies.

Interface

Move Keys—Moves keys in both horizontal and vertical axes, to change both timing and values.

Move Keys Horizontal—Constrains movement to the horizontal axis, to change timing.

Move Keys Vertical—Constrains movement to the vertical axis, to change values.

Scale Keys

Use Scale Keys to scale keys horizontally, changing the horizontal location and amount of time covered by selected keys. The horizontal location of the keys represents the frame in time at which the key action takes place.

The scale center for scale time is the current time set by the time slider. You can scale keys about any point in time by dragging the time slider before you use Scale Keys.

Procedure

To scale a selection of keys horizontally:

1. Right-click an animated object and choose Curve Editor.

2. In the Hierarchy list, highlight a track.

3. Scrub the time slider (page 3–701) to the frame to use as the scale center.

4. On the Track View toolbar, click Scale Keys.

5. Highlight one or more keys.

6. In the Track View Key window, drag any of the highlighted keys horizontally to scale, or press Shift and drag to add scaled copies of selected keys.

7. The scaling effect depends on the direction you drag with respect to the time slider location:
   
   - Drag away from the time slider location to expand keys' scaling.
   - Drag toward the time slider location to reduce keys' scaling.
• Drag past the time slider location to reverse the keys’ order and expand the keys away from the current time.

Scale Values

Scale Values is used to proportionally increase or decrease the vertical distance between selected keys on the function curves in Curve Editor. It uses the Scale Origin Line (page 2–506) as a movable reference point for the scale operation. Practically speaking, scaling values always creates spatial adjustments, rather than temporal. To scale in time, use Scale Time (page 2–570) instead.

Note: Scale Values is not available in Dope Sheet mode.

Procedure

To scale key values:

1. Select an object in the viewport, then right-click and choose Curve Editor.

2. Highlight one or more tracks, if necessary, and then highlight the keys you want to scale.

3. On the Curve Editor toolbar, click Scale Values.

4. Drag the Scale Values Origin line to where you want to scale values from or to.

5. Drag any highlighted key vertically to scale all of them.

Tip: If you use Lock Selection (page 2–555) after highlighting the keys, you can drag anywhere in the Key window to create the scale operation.

Add Keys (Curve Editor)

When Add Keys is active, you can click anywhere on a function curve to add a key at that location on the curve. Add Keys stays active until you click another mode.

If the curve is part of a multicurve controller, vertices are added to each curve at the time location where you clicked. For example, adding a key to the red X curve of a TCB Position track simultaneously adds keys to the green Y curve and the blue Z curve.

Tip: You can move an existing key while in Add Keys mode simply by dragging it.

Adding Keys to a Multicurve Controller

The value of each key is set by one of the following conditions:

• Keys added between keys receive the interpolated value shown by the function curve at that location.

• Keys added before the first or after the last key on the curve receive the same value as the nearest key.

• You can change a key value and/or time while adding it by dragging after clicking the curve.

Procedure

To add keys to a function curve:

1. In the Hierarchy list, highlight a track.

2. On the Track View toolbar, click Add Keys.

3. Click the function curve (Curve Editor) where you want to add the key.
If the highlighted curve is part of a multicurve controller, vertices are added to each curve at the time location where you clicked. For example, if you are using a Bezier Position controller, adding a key to the red X curve of a Position track simultaneously adds keys to the green Y curve and the blue Z curve.

**Show Tangents**

Show Tangents lets you view adjust the tangents of highlighted vertices in Curve Editor.

**Custom Tangent**

You can assign the Custom Tangent type to any controller that displays keys on a curve. Highlight the key on the curve and then click the Set Tangents To Custom icon on the Key Tangents: Track View toolbar to display the handle controls.

The tangent handles can be either continuous or discontinuous. To make a handle discontinuous, hold down the `Shift` key when you move it.

- Continuous handles behave like a single lever with its pivot point at the key location. Moving either end of the handle also moves the opposite end, maintaining the continuity of the tangent. The function curve, and the animation it represents, moves smoothly through a key with continuous tangent handles.
- Discontinuous handles behave like leaves on a hinge, with the hinge pin at the key location. Each end moves independently of the other.

To convert a discontinuous tangent to a continuous tangent, change the tangent type from Custom to Smooth and then back to Custom again. This technique is performed at the key level and can affect unselected vertices if they belong to the same key as one of the selected vertices.

**Horizontal Bezier Handle Control**

When using the Custom Tangent type, a tangent handle can be moved horizontally in length away from its keyframe to affect the shape of the function curve. This affects the amount of
influence the keyframe has over the interpolation between keyframes.

This feature can be used to aid in the slow-in and slow-out workflow of traditional animation. For example, suppose you're animating a ball bouncing up and down on the world's Z axis. On frame 1, the ball is on the ground; on frame 8, the ball is in the air; on frame 16 the ball is back on the ground. You could adjust the tangents for frame 8 so that their length pulls more of the curve towards its keyframe and away from the keyframes on frame 1 and 16. When rendered, the ball will be more visible on screen near the top of its bounce and blurrier near the points where it touches the ground.

Procedures

To assign a Custom tangent type:

1. Open the Curve Editor.
2. In the Hierarchy list, highlight a track that uses any controller that displays keys on the curve.
3. Highlight one or more keys on the curve.
4. On the Key Tangents: Track View toolbar, click Set Tangents to Custom.
   The handles are now all Custom and available for editing.
Tip: If a highlighted key has Auto Tangency set, you can just move its handle to instantly convert the key to Custom. For selections of multiple keys, choose Lock Tangents, then move any handle to convert all the keys to Custom tangency.

To edit the horizontal length of a Bezier handle:

1. Assign a Custom Tangent type to the key you want to edit on the function curve, or highlight a key that already has one.
2. Make sure Show Tangents is on. The toggle is located on the Track View toolbar.
3. Highlight the key on the function curve.
   Tangent handles appear on the highlighted keyframe.
4. Move one of the handles horizontally away from its key.

Interface

Show Tangents—Displays the tangents of highlighted vertices, whereupon you can adjust the tangents by dragging the handle endpoints.

By holding down the [Shift] key, you can edit the tangents handles separately.

Lock Tangents

Lock Tangents lets you manipulate handles of multiple vertices simultaneously. When Lock Tangents is active, dragging a tangent handle affects the handles of all highlighted keys. When Lock Tangents is inactive, dragging a tangent handle affects only that handle’s key.

Procedure

To drag discontinuous tangent handles:

1. Highlight one or more keys in the Curve Editor.
   Hold down the [Ctrl] key to add to the selection set.
2. Click Lock Tangents to set one of the following modes:
   • Off: Dragging a tangent handle affects only the single key displaying the handle.
On: Dragging a tangent handle affects both handles of all selected keys.

Apply Ease Curve / Apply Multiplier Curve

Apply - Ease Curve and Apply - Multiplier Curve (available from the Curves menu in the Curve Editor) create an ease curve or multiplier curve track. These tracks let you modify or intensify an existing animation track without changing the original track.

- A multiplier curve shifts the value of the original track up or down.
  Adjusting the multiplier curve increases or decreases the “intensity” of the original track.

- An ease curve shifts the time of the original track left or right.
  Adjusting the ease curve changes time. The value of the ease curve at a particular frame is a frame value from the original track. For example, if the ease curve is 0 at frame 0 and 10 at frame 10, the original track plays at its original speed. If the ease curve value at frame 10 increases to 20, the original track plays to frame 20 by frame 10: it has been sped up by a factor of two.

Once you apply an ease or multiplier curve, you can edit its keys, ranges, and properties just like any other animation track.

One use of ease and multiplier curves is to blend between the effects of different controllers. This can be an aid to nonlinear editing.

Procedure

To apply an ease curve or a multiplier curve:

1. In the Curve Editor Hierarchy list, highlight the tracks you wish to ease or intensify.
   
   Not all controller items can receive ease or multiplier curves. For example, the Path Constraint position controller cannot receive an ease or multiplier curve, but its subordinate Percent controller can. If the highlighted controller is incapable of receiving ease or multiplier curves, nothing happens when you apply the curve.

2. From the Curves menu, choose Apply - Ease Curve or Apply - Multiplier Curve.

3. In the Controller window expand the highlighted tracks to view the ease curve.

4. Hold down the Ctrl key and click the ease curve and controller tracks.

5. Adjust the keys on the ease curve and watch the result in the controller curve.
   
   Use a Multiplier curve to intensify an effect, or an ease curve to make less of an effect.
   
   Tip: Use Step interpolation to use the ease curve to turn tracks on and off.

Interface

Apply - Ease Curve—Applies a curve to alter the timing of the selected function curve. Ease curves vary the timing of a superior function curve. A normal function curve charts an animated parameter value over time. An ease curve charts changes to the timing of a function curve over time.

Apply - Multiplier Curve—Applies a curve to scale the value of the selected function curve. The value of a multiplier curve is a scale factor applied to the value of its superior function curve.

You apply ease and multiplier curves in Curve Editor mode. Once you apply an ease or multiplier
curve, you can edit its keys, ranges, and properties, as with any other animation track.

Remove Ease/Multiplier Curve

Remove (Ease/Multiplier Curve) lets you delete an ease or multiplier curve at any time.

Procedure

To delete an ease or multiplier curve:
1. In the Hierarchy list, select one or more ease or multiplier curve tracks.
2. On the Track View menu bar, choose Curves > Remove.
   The selected Ease or Multiplier curve is removed.
Tip: You can use On/Off (Curves) (page 2–585) to turn off the ease or multiplier affect without removing the curve.

On/Off (Curves)

Use On/Off when you want to work with the original function curve rather than a curve altered by ease and multiplier curves. A disabled curve has no effect on its assigned track, but can be enabled to restore the effect.

Procedure

To toggle the active state of an ease or multiplier curve:
1. In the Hierarchy list, highlight one or more ease or multiplier curves.
2. From the Curves menu choose On/Off.

If you also have the parent track selected (the transform that has the ease applied), you will see the difference in the curve when you turn the ease or multiplier off.

Ease Curve Out-of-Range Types

Ease Curve Out-of-Range Types displays a dialog that lets you assign out-of-range types for the current ease curve (page 3–932).
Ease and multiplier curves use the same out-of-range types as other controller tracks. See Parameter Curve Out-of-Range Types (page 2–551).
You will usually want to use the same out-of-range type for an ease curve that you use for its superior function curve.

Procedure

To set the out-of-range type for an ease curve:
1. Highlight one or more ease curve items in the Hierarchy list.
2. From the Curves menu choose Ease Curve Out-of-Range Types.
3. Do one of the following.
   • Click an out-of-range type image to apply that type to both the incoming and outgoing curves of the ease curve.
   • Click the left arrow button below an out-of-range type image to apply it to only the incoming curve of the ease curve.
   • Click the right arrow button below an out-of-range type to apply it to only the outgoing curve of the ease curve.
Chapter 12: Animation

Interface

Constant—Holds the values at the ends of the range for all frames. Use Constant when you want no animated effect before or after the range. The time value at start of the range is held for all frames before the range, and the time value at the end of the range is held for all frames after the range. Constant is the default out-of-range type for multiplier curves.

Cycle—Repeats the same animation as within the range. Use Cycle when you want an animation to repeat exactly.

Loop—Repeats the same animation as within the range but interpolates between the last key and the first key of the range to create a smooth loop. Use Loop with an extended range to produce smoothly repeating animation.

Ping Pong—Alternates between a forward and backward repeat of the animation within the range. Use Ping Pong when you want your animation to alternate back and forth.

Linear—Projects the animation value along a line tangent to the ease or multiplier curve at the end of the range. Use Linear when you want the animation to enter and leave the range at a constant velocity.

Relative Repeat—Repeats the same animation as within the range but offsets each repetition by the value at the end of the range. Use Relative Repeat to create animations that build on each other as they repeat.

Identity—Projects the ease curve along a line with a slope of 1.0 from either end of the range. This causes time to flow at a normal, constant rate outside the range of the ease curve. Use Identity when you want the ease curve to be a localized, non-repeating effect.

Identity for an ease curve produces an effect similar to constant for other types of curves. Identity is not available for multiplier curves; it is the default Out-of-Range type for ease curves.

Multiplier Curve Out-of-Range Types

Multiplier Curve Out-of-Range Types displays a dialog that lets you assign out-of-range types for the current multiplier curve (page 3–978).

Ease and multiplier curves use the same out-of-range types as other function curves. You will usually want to use the same out-of-range type for a multiplier curve that you use for its superior function curve.

Procedure

To set the out-of-range type for a multiplier curve:

1. Highlight one or more multiplier curve items in the Hierarchy list.
2. From the Curves menu choose Multiplier Curve Out-of-Range Types.
3. Do one of the following.
   - Click an out-of-range type image to apply that type to both the incoming and outgoing curves of the multiplier curve.
   - Click the left arrow button below an out-of-range type image to apply it to only the incoming curve of the multiplier curve.
• Click the right arrow button below an out-of-range type to apply it to only the outgoing curve of the multiplier curve.

Interface

<table>
<thead>
<tr>
<th>Out-of-Range Types</th>
<th><img src="image" alt="Constant" /></th>
<th><img src="image" alt="Cycle" /></th>
<th><img src="image" alt="Loop" /></th>
<th><img src="image" alt="Ping Pong" /></th>
<th><img src="image" alt="Linear" /></th>
<th><img src="image" alt="Relative Repeat" /></th>
</tr>
</thead>
</table>

**Constant**—Holds the values at the ends of the range for all frames. Use Constant when you want no animated effect before or after the range. The time value at start of the range is held for all frames before the range, and the time value at the end of the range is held for all frames after the range. Constant is the default out-of-range type for multiplier curves.

**Cycle**—Repeats the same animation as within the range. Use Cycle when you want an animation to repeat exactly.

**Loop**—Repeats the same animation as within the range but interpolates between the last key and the first key of the range to create a smooth loop. Use Loop with an extended range bar to produce smoothly repeating animation.

**Ping Pong**—Alternates between forward and backward repetition of the animation within the range. Use Ping Pong when you want your animation to alternate back and forth.

**Linear**—Projects the animation value along lines tangent to the ease or multiplier curve at the limits of the range. Use Linear when you want the animation to enter and leave the range at a constant velocity.

**Relative Repeat**—Repeats the same animation as within the range but offsets each repetition by the value at the end of the range. Use Relative Repeat to create animations that build on each other as they repeat.

**Freeze Non-Selected Curves**

Freeze Non-Selected Curves makes all non-highlighted curves uneditable. Default=On. Freeze Non-Selected Curves is a selection modifier and has the following properties:

• Non-highlighted curves display as dashed lines.

• You can manipulate vertices on highlighted curves only in the Edit window.

• You highlight other curves by clicking their icons in the Hierarchy list.

Turn Freeze Non-Selected Curves off when you want to be able to edit multiple curves without having to select them all. Turn Freeze Non-Selected Curves On when you have multiple vertices on multiple curves all in the same place.

**Procedure**

**Example: To freeze non-selected curves:**

1. Animate an object’s position.

2. From the Graph Editors menu, choose Track View - Curve Editor. On the Options menu, make sure Auto Expand > Selected Objects Only/Transforms/XYZ Components are all on.

   The X/Y/Z position tracks are all highlighted, and their curves appear in the Key window. You can drag keys on any curve.

3. On the Display menu, make sure Hide Non-Selected Curves is on. This is the default setting.
4. In the Hierarchy list, click the X Position track icon.
   Now only the red X Position curve is visible.
5. From the Display menu, choose Show Non-Selected Curves.
   The other two curves reappear, and are editable.
6. From the Display menu, choose Freeze Non-Selected Curves.
   The Y Position and Z Position curves remain visible, but display as dashed lines.
7. Position the mouse cursor over a vertex on the Y Position or Z Position curve.
   The cursor doesn't change to a crosshair, indicating that you can't modify the vertex.
8. In the Hierarchy list, click the Y Position track icon and then Z Position track icon.
   All three remain visible, but in each case the two non-highlighted tracks display as dashed lines, and are not editable.

---

**Status Bar/View Controls**

**Track Selection: Track View Toolbar**

Zoom Selected Object (page 2–588)
Select By Name (Track View) (page 2–589)
Track Sets List (page 2–590)
Track Sets Editor Dialog (page 2–591)

**Key Stats: Track View Toolbar**

Key Time Display (page 2–594)
Value Display (page 2–594)
Show Selected Key Statistics (page 2–595)

**Navigation: Track View Toolbar**

Pan (Track View) (page 2–595)
Zoom Horizontal Extents (page 2–595)
Zoom Value Extents (page 2–596)
Zoom Track View Key Window (page 2–596)
Zoom Region (Track View) (page 2–597)

---

**Zoom Selected Object**

With Track View already open to navigate to a particular object, select the object in the viewport. > Navigation: Track View toolbar > Zoom Selected Object

Use Zoom Selected Object to place the currently selected object at the top of the Hierarchy list in the controller window.

In Dope Sheet mode, Zoom Selected Object affects the Hierarchy list as well as the Edit window, but in the Curve Editor, it affects only the Hierarchy list. This function scrolls the hierarchy to place...
the track of the currently selected object at the top of the list. If the object is a child of a closed hierarchy, the hierarchy is opened to display the selected object. If more than one object is selected in the scene, the uppermost selected object in the Hierarchy list is placed at the top of the list. If no objects are selected, nothing happens. This function works only on object tracks.

Procedure

To place the selected object at the top of the Hierarchy list:

1. Select an object in the viewports.

2. Open Track View, and then click Zoom Selected Object.

   The object is placed at the top of the Hierarchy list.

   This option is handy to quickly find an object in a hierarchy, such as a character's finger, and place it at the top of the Hierarchy list.

Select By Name (Track View)

With Select By Name you can highlight tracks in the Hierarchy window by entering the track names (including optional wildcards) in the editable field. If the Controller Type display is active in the Filters options, you can specify by controller type as well.

Select By Name using wildcard

Notes

- The name selection is not case-sensitive, except for text within parentheses.
- Only those tracks that are open and displayed can be selected.
- You can use wildcard characters. For example: Seat selects all objects with Seat in the beginning of the name.
- (Cone01)Position selects only the Position track under Cone01.
- (Cone*)Position selects the Position track under all objects that begin with "Cone"
- You can include multiple names in your selection if you separate them with commas; for example: Cone,Box,Sphere.

Procedures

To highlight all the tracks in a scene:

- Enter * in the Select by Name field in the Track Selection toolbar.

   All the tracks are selected at once.
Example: To highlight and display Position tracks for three objects:

1. Create three boxes.
   By default, the boxes are named Box01, Box02, and Box03.
2. On the main toolbar, click Curve Editor (Open).
3. In the Track View Hierarchy list, expand the hierarchies for the three box objects.
4. In the Select By Name field, type (Box*)p.
   All the Position tracks are highlighted.
5. On the Track View toolbar, right-click Filters and choose Selected Tracks Only in the dialog.
   The Position tracks for the three boxes are displayed at the top of the Hierarchy list.

Example: To highlight multiple tracks using comma-separated name selections:

1. Create a box.
2. On the main toolbar, click Curve Editor (Open).
3. In the Track View Hierarchy list, expand box01’s hierarchy to see all Transform children tracks.
4. In the Select By Name field, type x pos, y rot, scale.
   The box’s X Position, Y Rotation, and Scale tracks are highlighted. The commas placed between each name act as Boolean addition (“OR”) operators, allowing multiple names in one selection.

Track Sets List

You can assign a name to the current track selection, and then later reselect those tracks by choosing the name of the respective track set from the list.

Track Sets List

You can also create and edit track sets with the Track Sets Editor dialog (page 2–591).

Using Key Filters with Track Sets

If you are animating track sets using Key Filters in Set Key mode (page 3–718), the filters dictate which track set members are keyable, because they take precedence over track sets.

Set Key Filters

Only the track set members specified in the Key Filters list are keyable.

Procedures

To assign a name to a track set:

1. Highlight one or more tracks in the Track View Controller window.
2. Click in the Track Set List field on the Track View toolbar (page 2–535).
3. Enter a name for your track set. The name can contain any standard ASCII characters,
Track Sets Editor Dialog

Curve Editor Track Selection toolbar > Edit Track Set

The Track Sets Editor dialog is a modeless dialog (page 3–973) that lets you create and edit animation track groups called track sets. This feature facilitates working on multiple tracks at a time, because you can recall your tracks without the need to select them individually.

Tip: As your projects grow in size, you can also use track sets to help organize your animations by regrouping them under reference dates or versions such as Walk_Animation_v5.0 or Baseball_Hit_2005/07/01.

Within the Track Sets Editor dialog, you can browse track set listings, add or remove tracks to/from a track set, highlight track set members based on selections from the Hierarchy list, and vice-versa.

See also
Track Sets List (page 2–590)

Procedures

To create a track set from selected tracks:

1. In the Track View Controller window, highlight tracks to group as a track set.

2. Click Edit Track Set.

3. In the Track Sets Editor dialog, click Create A New Track Set.

To retrieve a track set:

1. In the Track Sets List, click the arrow.

2. On the list, click a name.

The respective tracks are highlighted in the Track View Controller window.

To edit a track selection:

You can change a track selection using track sets and the Ctrl and Alt keys.

1. Highlight one or more tracks in the Track View Controller window.

2. Open the Track Set List by clicking the arrow.

3. Press and hold Ctrl and then click a name in the list.

The track set members are added to the current track selection.

4. Press and hold Alt and then click a name (either the same or another) in the list.

The track set members are subtracted from the current track selection.

To edit track sets:

- On the Track View toolbar, click Edit Track Set to display the Track Sets Editor dialog (page 2–591).

including letters, numerals, symbols, punctuation, and spaces.

Note: Names are case-sensitive.

4. Press Enter to complete the track set.

You can now highlight another combination of tracks and repeat the process to create another track set.

To create a track set from selected tracks:

1. In the Track View Controller window, highlight tracks to group as a track set.

2. Click Edit Track Set.

3. In the Track Sets Editor dialog, click Create A New Track Set.
Chapter 12: Animation

4. Expand the new track set.
   A new track set appears containing your selected tracks.

To edit the contents of a track set:

This procedure follows from the previous procedure, and focuses on adding and removing tracks to/from your track set.

1. In the Track View Controller window, highlight a few tracks to add to your track set. Make sure the tracks are not already part of it.

2. In the Track Sets Editor dialog, highlight your track set or any of its members, and then click Add The Track View Selection To The Current Track Set.
   The highlighted tracks are now members of your track set.

3. Click Remove The Track View Selection From The Current Track Set.
   The highlighted tracks are now removed from the track set.

To locate tracks in the Track View or the Track Sets Editor:

This procedure is a continuation of the previous procedures and explains how you can use the Track Sets Editor to quickly locate your tracks in the Hierarchy list and vice-versa. This is useful for managing scenes comprised of many tracks that span across multiple track sets.

1. Create two track sets each containing tracks. Make sure one track is common to both track sets.

2. In the Track View Controller window, highlight the common track.
   In the Track Sets Editor dialog, click Highlight Tracks Selected In The Track View.
   The common track is highlighted in both track sets.

3. Highlight another track set member and click Select The Current Track Or Track Set In The Track View.
   The respective track in the Controller window is highlighted.
Interface

The Track Sets Editor dialog window displays all current track sets. To expand or collapse the track list for a set, click the plus (+) or minus (-), button next to the track set name.

Create A New Track Set—Adds a new track set comprising any highlighted tracks in the Hierarchy list.

Only leaf (page 3–951) tracks can be part of a track set. If you highlight a non-leaf parent track when the track set is created, all its children leaf tracks are added instead.

Delete Track Sets Or Tracks—Removes a highlighted track set or track set member.

Note: Deleting a track set member does not delete it in the Track View.

Add The Track View Selection To The Current Track Set—Combines a highlighted track from the Controller window to the current track set.

Only leaf tracks can be added to a track set. If you highlight a non-leaf parent track to be added to the track set, all its children leaf tracks are added instead.

Remove The Track View Selection From The Current Track Set—Deletes a track set member from the current track set. The track itself must be highlighted in the Controller window.

Highlight Tracks Selected In The Track View—Highlights a track set member based on the current Track View selection. If a track is shared between track sets, all track set members are highlighted.

Select The Current Track Or Track Set In The Track View—Highlights a track in the Controller window based on the current track set member selection.
Key Time Display

Track View > Curve Editor or Dope Sheet > Key Stats: Track View toolbar > Key Time Display (field on left)

The Key Time editable field (the field on the left) displays the frame number (position in time) of the selected key. You can enter a new frame number or enter an expression to move the key to a frame.

Using Expressions in the Time and Value Fields

You can enter any expression in the time and value fields. The variable \( n \) stands for the key time or value. An expression can be as complex as you want, and can involve any function the expression controller (page 2–320) uses. For example, you could enter an expression such as: \( n/2 + \sin(n) \times 40^n \).

The expression parsing in the time field works only when Time Configuration (page 3–725) > Time Display is set to Frames. The expression parser doesn’t understand SMPTE or Frame:Ticks.

Procedures

To move a key to a specific frame:
1. In Track View, highlight a key.
2. In the Key Time Display, enter the frame number you want to move the key to.
3. Press Enter.

The key (and, in Dope Sheet mode, any associated keys) moves to the new time.

To move keys ahead 10 frames:
1. In the Track View Key window, highlight keys.
2. In the Key Time field, type \( n+10 \).

Selected keys are incremented by 10 frames.

Value Display

Track View > Curve Editor or Dope Sheet > Key Stats: Track View toolbar > Value Display (field on right)

Value Display (the field on the right) displays the value, or position in space, of a highlighted key. This is an editable field. You can enter a new number or expression to change the value of selected keys.

Procedures

Example: To move an object in space using Value Display:
1. In the Track View (either mode) Hierarchy list, expand the Position track of an animated object. In Curve Editor mode, if Show Non-Selected Tracks is not active, highlight a track, if necessary, so the keys are visible.
2. Highlight an X, Y, or Z Position key.
3. Enter the value you want in the Value Display and press Enter.

The new value takes effect. If the time slider is at or near the same frame as the key, the change is visible in the viewports.

Example: To add 10 to the values of specific keys:
1. In Track View, either mode, highlight the keys to edit.
2. In the Value Display field, enter \( n+10 \).

Each key’s value is incremented by 10. Simply entering 10 would give each key a value of 10.
Show Selected Key Statistics displays the statistics represented by the currently selected keys in the Key window of the Curve Editor.

The frame number and value are displayed to the right of the key in the Key window. For example, 68, 40.620 (frame=68, value=40.620).

**Procedure**

**To show selected key statistics:**

1. On the Key window of the Curve Editor, select any key or set of keys.
2. On the Key Stats: Track View toolbar, click Show Selected Key Stats.

The key statistics are displayed next to each key.

Drag horizontally in all modes to slide the view forward and backward in time. Drag vertically to slide the view up and down in value.

**Zooming and Panning with a wheel mouse**

You can use the wheel on a wheel mouse to zoom and pan the Track View Key window. Drag with the wheel to pan, and roll the wheel to zoom. (If you have a standard three-button mouse, use Ctrl+Alt+middle mouse button to zoom.)

**Procedure**

**To pan in the Key window:**

2. Position the mouse cursor over the Key window, and then press and drag to pan.

**Zoom Horizontal Extents**

Zoom Horizontal Extents is a flyout containing the Zoom Horizontal Extents and Zoom Horizontal Extents Keys buttons.

Use Zoom Horizontal Extents to show only the active time segment (page 3-904), and use Zoom Horizontal Extents Keys to show all keys, including those outside the active time segment.

**Procedure**

**To display the active time segment in the Key window:**

- On the Track View status bar, select Zoom Horizontal Extents.
Chapter 12: Animation

The active time segment (lighter background color) is centered in the Key window.

Interface

[ ] Zoom Horizontal Extents—Adjusts the magnification of the Track View Key window horizontally so that all of the active time segment is visible at once.

[ ] Zoom Horizontal Extents Keys—Scales the Track View Key window horizontally to display the full range of all animation keys. Depending on your animation, this view could be larger or smaller than the active time segment.

Zoom Value Extents

Track View > Curve Editor > Navigation: Track View toolbar > Zoom Value Extents

Zoom Value Extents is a flyout containing the Zoom Value Extents and Zoom Value Extents Range buttons.

In Function Curves mode, Zoom Value Extents adjusts the size of the Track View Key window vertically so that you can see the full height of the curve. Zoom Value Extents Range also adjusts the window vertically but it zooms only to the height of the keyframes that are currently in view.

Note: In Dope Sheet mode, Zoom Value Extents and Zoom Value Extents Range serve no function.

Procedures

To zoom to the height of the curves:
1. In the Hierarchy list, highlight the tracks to display.
2. On the Track View status bar, click Zoom Value Extents.

The Key window scales vertically to display the function curves.

This is particularly useful if you are zoomed in and need to see all the keys again. There is no undo for view changes that occur in the Key window, so the Zoom Extents button can serve the function of resetting your view.

To zoom to the height of the keyframes that are currently visible:
1. In the Hierarchy list, highlight the tracks to display.
2. On the Track View status bar, click Zoom Value Extents Range.

The Key window scales vertically to the height of the keyframes in view.

This is useful if you want to focus on working with one section of your animation curve.

Zoom Track View Key Window

Main toolbar > Curve Editor or Dope Sheet > Navigation: Track View toolbar > Zoom

In Track View, the Zoom controls are available from a three-button flyout. You can zoom your view of time horizontally (Zoom Time), vertically (Zoom Values), or in both directions simultaneously (Zoom). Drag to the right or upward (Zoom Values) to increase magnification, or to the left or downward (Zoom Values) to decrease magnification.

Zooming occurs around the cursor location.
Note: All three zoom modes work in Curve Editor, but only Zoom and Zoom Time work in Dope Sheet.

Tip: If you have a three-button mouse, you can also zoom uniformly by using [Ctrl+Alt]+middle mouse button or by scrolling with your mouse wheel in the Curve Editor.

Tip: You can also zoom exclusively in time (left and right) or in value (up and down) by holding down [Ctrl] or [Shift] respectively while scrolling with your mouse wheel in the Curve Editor.

Procedure
To zoom in on time:
1. On the Navigation: Track View toolbar, choose Zoom Time from the flyout.
2. Click and drag to the right in the Track View Key window.
   Your view of time expands horizontally in the Key window.

Interface
Zoom—Zooms your view of time and values simultaneously. Zoom remains active until you right-click to cancel or click another option. The Zoom button is yellow while active.

Zoom Values—In Curve Editor, zooms the contents of the keys window vertically. Drag upward to increase magnification, or downward to decrease magnification.

Zoom Time—Zooms the contents of the Key window horizontally.

Zoom Region (Track View)
Track View > Curve Editor or Dope Sheet > Navigation: Track View toolbar > Zoom Region

Zoom Region lets you drag a region in the Key window to scale that region to fill the window. Zoom Region remains active until you right-click to cancel or click another option. The Zoom Region button is yellow while active.

In Curve Editor mode, both time and value are scaled to fit the Key window. In Dope Sheet mode, only time is scaled to fit the Key window.

Procedure
To zoom a region of the Key window:
1. On the Navigation: Track View toolbar, click Zoom Region.
2. Drag a window in the Key window.
   The region zooms to fill the Key window.
   Tip: There is no undo for view changes in the Track View windows. Use the Zoom, Zoom Region, and Zoom Extents tools to navigate the Key window.

Managing Track View Windows

New Track View
Graph Editors menu > Track View > New Track View

New Track View opens a new, untitled Track View (page 2–501) window. A scene in 3ds Max can have up to 13 Track View windows. You can choose
these by name from the Graph Editors > Saved Track Views (page 2–599) submenu. New Track View is disabled if the scene already has 13 Track View windows.

You can name a Track View window by typing in the editable field at the right end of the Track View toolbar.

Procedures

To create a new Track View window:

- Click Track View > New Track View.

  The software opens a new, untitled Track View window, regardless of whether you have closed other Track View windows.

To name a Track View window:

- Type the name in the edit box at the right end of the Track View toolbar.

  As soon as you type the name in, it is stored in the Saved Track Views list.

Delete Track View

Graph Editors menu > Delete Track View

Delete Track View displays the Delete Track View dialog (page 2–598), which lets you delete one or more stored Track View windows (page 2–501).

Procedure

To delete a Track View window:

1. From the Graph Editors menu, choose Delete Track View.

   The Delete Track View dialog opens.

2. In the Delete Track View dialog, highlight one or more Track View windows.

3. Click OK to delete the Track View windows you chose.

Delete Track View Dialog

Graph Editors menu > Delete Track View

The Delete Track View dialog lets you delete one or more stored Track View (page 2–501) windows by choosing their names from a list.

Procedure

To delete a Track View window:

1. Choose Track View > Delete Track View.

2. In the Delete Track View dialog, choose the name of one or more Track View windows.

3. Click OK to delete the highlighted Track View windows.

Interface

Drag a selection, use [Shift] + click to select additional adjacent Track View windows, or [Ctrl] + click to toggle a selection.
Saved Track Views

Graph Editors menu > Saved Track Views > Choose the named Track View from the list.

Saved Track View lets you recall various Track View windows that you save by naming them.

It is different from saved Track View layouts, which are recalled by right-clicking the toolbar and choosing Load layout.

Saved Track View windows are saved with the MAX file.

Procedure

To save a Track View window:

1. In either Dope Sheet or Curve Editor, enter a name in the Name: Track View field at the upper right.
   Tip: If the Name field is not visible, right-click the toolbar and choose Show Toolbars, then choose Name: Track View from the list. This toolbar can float or dock, as you like.

2. Close Track View.

3. To recall the saved Track View window, from the Graph Editors menu, choose Saved Track Views, and then the desired window name.

Track View Customization

The Track View user interface is fully customizable. There are many ways you can change the UI to suit your needs.

A customized Track View user interface:

1. Toolbar docked left
2. Menu bar
3. Key window (Hierarchy list hidden)
4. Floating toolbar
5. Scroll bar
6. Toolbar docked right

You can hide or display UI elements as you need to use them. Customization tools are available from the Track View menu bar or from several Track View toolbars. You can float or dock the toolbars to the top, bottom, left, or right of the application window, for example, floating a toolbar so it is closer to where you are working.

To customize the Track View UI, right-click the menu bar or the blank space to the right of the Track View toolbars. A right-click menu is displayed, with commands for the tools you need to perform your customization.

Track View Toolbar Right-Click Menu

You can use commands on the toolbar right-click menu (page 2–603) to perform most Track View UI customization tasks. Move your cursor over the blank space to the right of the Track View toolbars and right-click to display this menu.

Show UI Elements

Toggles on and off the display of Track View user interface elements. For example, you can hide or
show the menu bar, scroll bars, the controller and keys windows, and the time ruler.

**Menu Bar**
The menu bar gives access to most of the tools also found on the toolbars. The menu bar can be displayed or hidden in the Curve Editor, Dope Sheet, or track bar. The menu bar is context-sensitive, so it changes its display depending on which Track View mode is active.

**Scroll Bar**
Standard Windows scroll bars can be displayed or hidden for the Track View window. These are useful for navigating complex or lengthy windows.

Use the Pan hand button to scroll when these are not visible. The middle mouse button can also be used to activate the pan hand to scroll this window.

**Windows**
There are two side-by-side display areas in Track View. They are the Controller window and the Key window. The Controller window contains the Hierarchy list with labeled tracks. The Key window displays the keys either as curves in the Curve Editor, or as boxes or ranges on a grid in Dope Sheet mode. Use Show UI Elements, available from the toolbar right-click menu, to hide either window.

**Time Ruler**
A movable time ruler is provided. To measure time, you can move the time ruler close to the keys or curves when working zoomed in. Default=on.

**Track View - Curve Editor Toolbars**
You can display Curve Editor toolbars (page 2–535) for quick access to tools.

The Curve Editor toolbars that you can display or hide, dock or float, from the right-click menu include the following:

- **Name** toolbar—Enter a name in this field to create a named Track View window. You can recall the saved Track View window by choosing Graph Editors menu > Saved Track View (page 2–599) submenu. This option is also available in Dope Sheet mode.

- **Navigation** toolbar—Use these tools to pan (page 2–595) and zoom the Key window (page 2–596), or zoom to the extents of the time (page 2–595) or the values (page 2–596). This option is available in both Track View modes.

- **Key Stats** toolbar—Track View provides tools for the display and type-in transform of key values (page 2–594). This option is also available in Dope Sheet mode.

- **Tangents** toolbar—Track View gives you quick access to different tangency types of keys (page 2–536). This toolbar is most useful when floating near the curves. This option is also available in Dope Sheet mode.

- **Controllers** toolbar—Track View has tools to copy, paste,
assign, delete, and make controllers unique (page 2–540). This option is also available in Dope Sheet mode.

Selection—Track View gives you tools to select tracks by typing in the name of an object (page 2–588). This option is also available in Dope Sheet mode.

Keys—Track View provides the tools to move (page 2–579), scale (page 2–580), and slide keys (page 2–558), scale values (page 2–581), add keys (page 2–581), draw curves (page 2–582), and reduce keys (page 2–572). This toolbar also has the Filter button, which lets you limit the display in the Controller window. A similar option is available in Dope Sheet mode (page 2–538) with different and fewer controls.

Curves—Track View provides tools to select and lock keys and curve handles (page 2–536), as well as to make tracks keyable (page 2–531), and to apply parameter curve out-of-range types (page 2–551).

Tools—Track View gives you tools to create or remove Note and visibility tracks, snap frames, lock selection, properties, and Track View utilities. This toolbar is hidden by default.

Dope Sheet Toolbars

There are 11 toolbars that can be displayed when in Dope Sheet mode. In addition to the ones listed above for the Curve Editor, you can also choose to display the following:

- **Keys**—Dope Sheet displays the tools to move, add, and scale keys (page 2–538), the Filters button (page 2–541), and the buttons that let you choose between Edit Keys (page 2–554) and Edit Ranges (page 2–573) options for Dope Sheet.

- **Time**—Track View provides tools to select and work with time (page 2–539). Time can be selected, inserted, cut, copied, pasted, scaled, reversed, or removed. This toolbar works only in Dope Sheet mode.

- **Ranges**—Here are the tools to edit (page 2–573), position (page 2–574), and recouple ranges (page 2–574).

- **Display**—Dope Sheet holds tools to modify subtree (page 2–528) and modify child keys (page 2–529), lock selection (page 2–555), snap frames (page 2–554), and display keyable icons (page 2–531).

Soft Selection Toolbar

Both the Curve Editor and Dope Sheet Edit Keys mode take advantage of soft selection of keys. If
you choose Keys menu > Use Soft Select, then choose Soft Selection Settings (page 2–525), the Soft Selection Settings toolbar is displayed. This toolbar is accessible only from the Keys menu, not from the right-click menu. If you want this menu to stay visible, save a Track View layout (page 2–602).

**Track Bar**

You can dock the Track View windows below the time slider and track bar by choosing Dock > Bottom from the toolbar right-click menu. You can dock multiple Track View windows using this technique.

You can also display a Track View window below the viewports by clicking the Open Mini-Curve Editor button at the upper left corner of the track bar. Using this method, the time slider and track bar are replaced with the Track View window. As with Dope Sheet and Curve Editor modes, you use the toolbar right-click menu to display or hide all Track View UI elements.

**Procedures**

**To save a Track View layout:**

1. Customize the Track View layout as you want.
2. When you want to save it, right-click the Track View menu bar or the blank area at the right of the Track View toolbar, and choose Save Layout As.
3. Enter a name you will remember.

**To reload a saved Track View layout:**

1. Right-click the Track View menu bar or the blank area at the right of the Track View toolbar and click Load Layout.
2. Choose the layout you want to display in Track View.

**To save a Track View window:**

You can save a particular Track View window, displaying to a particular set of tracks, by using the Name: Track View toolbar.

- Enter the name for the window in the Name field. When you close the window, you can reload it by choosing Graph Editors > Saved Track Views. Then choose the named window from the list.

Tip: Named Track View windows are saved with a file. Named layouts are independent of the file.

**To restore the default Track View user interface:**

If you have customized your Track View user interface and want to return to the original installed version, do the following:

1. In the \Program Files\Autodesk\3ds Max 9\ui\ folder, locate the file trackview.bak.
2. Copy the file and rename the copy trackview.ini.
3. In Windows Explorer or My Computer, right-click and choose Properties. Make sure the Attributes is not set to Read-only.

Tip: You can also right-click the Track View title bar and choose Load Layout > Default to return to the default layout. This works only if you have not saved over the default.

**To add a new menu bar name to a custom Track View layout:**

1. From the Customize menu, choose Customize User Interface.
2. On the Menus panel, click New to create a new menu. Enter the name of the menu in the New Menu field and click OK.
3. Using Notepad, open ui/trackview.ini, and navigate to the layout section. To affect the Curve Editor toolbar, choose the section named [default], or to affect the Dope Sheet toolbar, choose the section called [Dope Sheet layout].
4. Change the value of the "Menu Name" entry to the name of the menu you created in step 2. Save the layout after you are done and the changes will be persistent.

Tip: You can also make the Dope Sheet Editor point at a renamed menu bar by using MAXScript:

In the MAXScript Listener, type `trackviews.current.ui.menubar = "Dope Sheet - Menu Bar"`, substituting your menu bar name, and then press the Enter key.

Note: There is also a script that lets you choose menus from a list. Choose Customize menu > Customize User Interface, then on the Menus panel, set Group to Main UI and Category to Track View, and choose Load Menu Bar from the Action list. Select the Track View menu bar you want to customize from the drop-down list on the right. Drag the action to the right window and the menu bar will be customized.

---

**Track View Toolbar Right-Click Menu**

You can use commands on the right-click toolbar menu to perform most Track View UI customization tasks. Move your cursor over the blank space to the right of the Track View toolbars and right-click. This shortcut menu’s customization tools are as follows:

- **Dock**—Snaps the toolbars into position horizontally above or below the window, or vertically along the left or right window edge. Once toolbars are horizontally docked, they can be reordered by dragging and dropping them as you like. Also used to dock the window beneath the viewports.

- **Float**—Floats the selected toolbar.

You can float toolbars anywhere you like. You can also drag the double bars at the left of the toolbar to float the toolbar over the viewport.

- **Hide**—Turns off the display of the selected user interface element. Once something is hidden, you can redisplay it using Show UI Element or Show Toolbar on this menu.

- **Load Layout**—Loads a saved default, named, Function Curve, Dope Sheet, or track bar layout.

- **Save Layout**—Saves your customized layout, creating a new default layout. When you open a new Track View, this saved layout will be displayed.

Note: To restore the default 3ds Max layout, see To save a Track View layout: (page 2–602).

- **Save Layout As**—Saves your customized layout with a name you choose. When you’ve customized your layout, save it with an easily recognizable name, then you can return to it whenever you choose. Use Load layout to retrieve a saved layout.

- **Show UI Elements**—Toggles the display of Track View user interface elements. For example, you can hide or show the menu bar, scroll bars, the controller and Key windows, and the time ruler.

- **Add Toolbar**—Lets you display additional toolbars that you can create using commands the Customize User Interface pull down from the main menu bar.

- **Delete Toolbar**—Deletes the selected toolbar.

- **Show Toolbars**—Lets you choose which toolbars you want to display or hide.

Note: Some toolbars are hidden by default.
# Motion Mixer

The Motion Mixer allows you to combine motion data for biped and non-biped objects.

The Motion Mixer takes its design from the world of audio. When a song is recorded in a studio, each instrument is played and recorded separately. Each recording is called a **track**. The tracks are then put together in a sound mixer so they play simultaneously, or overlap one another. During the mixing process, the mixer operator can change the length or speed of a track, increase or reduce volume, move a track to another place in the song, or cause a track to fade in or out.

The Motion Mixer works in a similar way. For any object, you can add multiple **tracks** to the mixer, each holding a separate series of motion clips (**BIP files** and **XAF files**). You can trim clips to use only part of a motion, make the clips play slower or faster, or create transitions from one clip or set of clips to another.

You can also use the Motion Mixer to animate some body parts with one set of clips, and other body parts with other motions. For example, suppose you have two clips, one where the biped runs with its arms pumping by its sides, and another where the biped stands and cheers with its arms in the air. You can mix the leg and hip motions from the running motion with the arms from the cheering motion to make an animation of a biped cheering as he runs across a finish line.

**See also**

*Using the Motion Mixer (page 2–604)*

Motion Mixer Interface (page 2–628)

---

## Using the Motion Mixer

The Motion Mixer allows you to mix motion files (**BIP** and **XAF** files) for any biped or non-biped objects. These motion files are also called **clips**.
The Motion Mixer is comparable to an audio mixer. Motion clips can be cross-faded, stretched, layered, and finally, mixed down to a single clip.

The Motion Mixer works by placing motion files on tracks (page 3–1023). With the Motion Mixer, you can:

- Transition or fade between motions.
- Move motions in time.
- Trim a motion so only part of it is used.
- Vary the speed of a motion over time.
- Use animation from selected biped or non-biped body parts within a motion clip.
- Keep planted feet from sliding during foot-based transitions.

To see a biped motion in the Mixer applied to the biped in the scene, you must turn on Mixer Mode from the Biped rollout (page 2–936).

In the Motion Mixer, motions are imported and mixed for any objects in the scene. Once motions are mixed, you can pass the mix on to other biped (if it contains BIP files) and non-biped objects (if it contains XAF files), or save the mix to a MIX file.

**Blending Motions in the Mixer**

The Motion Mixer provides these types of motion blending.

- You can blend motion from one clip to another with a transition (page 3–1027). Transitions in the Mixer are similar to those used in the motion flow system (page 2–1026). The optimization feature can automatically find the best timing for a transition between two clips. When you make a transition between foot-based clips (clips where IK constraints keep the feet planted at certain times), you can cause the transition to focus on one foot or the other. See Working with Transitions (page 2–616).

- In biped animation, if a transition between foot-based clips causes the foot to slide or pop slightly during the transition, you can fix this problem with a mixdown (page 3–973) (flattening all tracks into one track). See Exporting Animation to the Biped (page 2–624).

- You can change the weight (page 2–619) of clips or tracks so they affect the animation more at some times than others. See Adjusting Track Weight (page 2–619).

- You can use only the part of a clip’s motion that affects specified body parts. See Filtering Mixer Tracks (page 2–612).

- When motions applied to a biped’s upper body vary greatly from motions on its lower body, the Mixer automatically compensates for discrepancies in balance. See Adjusting Biped Balance in the Mixer (page 2–622).

  **Note:** Balance parameters are available only when mixing biped objects.

**Transitions Between Foot-Based Clips**

The Motion Mixer excels in its ability to maintain smoothness of motion over transitions between foot-based clips. Foot-based clips use IK constraints to keep one or both feet locked down over the course of the motion.

For bipeds, the Mixer provides tools for maintaining foot positions during transitions:

- Computing the influence of balance from the upper to the lower body. Without this, layered motion tracks will appear to be artificially combined since out since the resulting motion will be plagued by the isolation of dynamics and improper balance.

- Mixdowns allow for precise elimination of the foot sliding with the aid of knee limit filtering to unnatural knee popping artifacts.

In short, the goal of the mixer is to assemble seamless, coherent character motion using
building blocks composed from other motion fragments.

For non-biped rigs and other 3ds Max objects, the Mixer provides velocity blends and sub-blends to maintain smooth and coordinated motion.

**Comparing the Motion Mixer and Motion Flow**

Both the Motion Mixer and *Motion Flow* (page 2–1026) can be used to create transitions between a consecutive series of BIP files. However, there are a few significant differences between the two features:

- With the Motion Mixer, several BIP files can be used at the same time to affect biped motion. Compare with Motion Flow, where only one BIP file, or a transition between two consecutive BIP files, affects the biped at any given time.
- With the Motion Mixer, you can specify that a BIP file will affect only one part of the body. This feature is not available in Motion Flow.
- In the Motion Mixer, you can use a mixdown to automatically lock feet during transitions between biped foot-based motions. Motion Flow does not perform this function.
- A Motion Flow network can be used in conjunction with the Crowd feature, giving the bipeds a choice of motions over the course of the simulation. The Motion Mixer does not generate motion for biped crowds.
- A Motion Flow network can be used to randomly generate different motion scripts for one or more bipeds. This feature is not available in the Motion Mixer.

Use the Motion Mixer when you want to create a specific animation for an object from several clips, or you want to specify that some motions be applied only to specific body parts. If you want to work with biped crowds or create random motion, use Motion Flow.

If you’re creating a straight series of transitions between motions, you can use either one. However, the Motion Mixer has additional tools for improving foot-based transitions.

**Opening the Motion Mixer**

You open the Mixer by either clicking the Mixer button on the Motion panel > Biped Apps rollout (page 2–935) or choosing Motion Mixer from the Graph Editors menu (page 3–682).

When you open the Mixer while a biped is selected, a trackgroup (page 3–1024), a clip track, and a balance track (page 3–914) are assigned to that biped. If a non-biped object is selected, the Mixer opens empty.

1. Trackgroup
2. Clip track
3. Balance track

These items are discussed in detail in the sections that follow.

**Procedures**

To access the Motion Mixer from the Motion panel:

1. Select a biped.
2. Access the Motion panel.
3. On the Biped Apps rollout (page 2–935), click the Mixer button.

The Motion Mixer opens, and displays the selected biped and two tracks. To learn about these tracks, see *Adding Tracks to the Mixer* (page 2–607).
Adding Tracks to the Mixer

In the Motion Mixer, you begin the mixing process by opening the Mixer, then adding objects to mix, and then loading motion clips to clip tracks (page 3–1023). One clip track is created automatically if a biped is selected while you open the Mixer, but you'll probably need more to hold all the motions you want to use with your mixed objects.

When you open the Mixer while a biped is selected, a *trackgroup* (page 3–1024), a clip track, and a *balance track* (page 3–914) are assigned to that biped. If a non-biped object is selected, the Mixer opens empty.

Types of Clip Tracks

There are two types of tracks to which you can add clips:

**Layer**—A track for a series of motions that do not need transitions between them. By default, a Layer track is created for a biped when you open the Mixer.

**Transition**—A tall track with room for two rows of clips. You can put one motion file on the top...
tier and another on the bottom, and place a
transition in the area where the two clips overlap.
Transitions on these tracks are similar to Motion
Flow transitions (page 2–1034) between clips.

Transition track

Each biped in the Mixer is automatically given
a balance track (page 3–914), used for adjusting
balance between clips in Layer and Transition
tracks. Clips cannot be added to the balance track.
Note: Balance tracks are only available for mixed
biped objects.

Procedures

To add a Transition or Layer track to a trackgroup:

• Right-click an existing track and choose one of
  the options for adding tracks from the pop-up
  menu.

To convert a clip track from one type to another:

• Right-click an existing track, and choose one
  of the options from the pop-up menu for
  converting tracks.

To add a biped to the Motion Mixer:

1. On the Motion Mixer toolbar, click Add
   Biped.

2. From the Bipeds dialog, choose the biped(s)
   you want to add to the Motion Mixer.
   Several bipeds can be added to the mixer at
   once. When you click OK, highlighted bipeds
   are added to the mixer. Each is automatically
   assigned a trackgroup, a clip track, and a
   balance track.

To add a non-biped object to the Motion Mixer:

1. On the Motion Mixer toolbar, click Add
   Max Objects.

2. From the Max Objects To Mix dialog, choose
   the object(s) you want to add to the Motion
   Mixer.
   Tip: You can save time if you first select your
   objects, and then open the dialog. This way, the
   objects are automatically highlighted.

3. Enter a mix name or leave the default one.
   When you click OK, the highlighted objects are
   added to the mixer under a single object mix.
   A track is automatically assigned to the object.
Importing Clips to the Mixer

You can bring motion clips (BIP and XAF files) into the mixer with any of these methods:

- Choose a file directly from the folder in which it resides.
- Choose a file from those you have placed in the Reservoir (page 2–626), a storage area for BIP and XAF files.
- Import motion from another biped in the scene. See Working with Clips in the Mixer (page 2–611).
- Import a motion flow script.

All clips imported for a single object are assigned a random, unique color. For example, all clips for one biped might be red, while those for another biped are blue. The color distinction makes it easier to work with multiple bipeds and non-biped objects in the Motion Mixer.

Biped rollout > Mixer Mode must be turned on in order to see the motion on the biped in viewports. This option is turned on by default when you open the Mixer from the Biped rollout (page 2–936).

The Motion Mixer might not display the entire active segment when it is first opened. To set the Mixer display to the extent of clips in the Mixer, click Set Range on the Motion Mixer toolbar.

Preparing BIP and XAF Files

To use a motion file with the Motion Mixer, it must first be saved as either a BIP or XAF file. Many BIP files come with 3ds Max; you can use these, or you can make your own. To find out how to create your own BIP files, see Loading and Saving BIP Animation (page 2–920). For more information of XAF files, see Saving and Loading Animation (page 3–472).

Importing XAF Files

Non-biped object assets are loaded into the Mixer using the Load XML Animation File dialog (page 3–474), from which you pick the desired XAF motion file to import. If the motion file needs an XMM mapping file, you can either choose an existing one or open the Map Animation dialog (page 3–478) to create a new file.

Tip: If you load multiple motion clips at the same time, you can pick a mapping file only once if all clips use the same.

Note: The Relative/Absolute and Replace/Insert options are unavailable when you import XAF files.

Note: Loading XAF clips from the Reservoir (page 2–649) follows the same workflow.

Interpreting Clip Names

When you load a clip into the Mixer, the clip appears on the track as a solid bar, with its name displayed on the clip.

Other information can appear on the clip, such as the start and end frames, and the clip scale (page 2–615). You can change the information that displays on the clip by clicking Preferences on the Motion Mixer toolbar, and changing the Clips options on the Mixer Preferences dialog (page 2–651).

You can use the same clip numerous times in the Mixer. Each version of the clip displays the name...
of the BIP file, followed by a number, such as 1 or 2. The name might also have the letter Z between the name and number. These suffixes tell you how the clip is interpreted by the Mixer.

When you load a biped clip from a file, you have the option of setting the lowest starting foot height to Z=0 (the construction plane). If you leave this option turned on, the clip's motion will be moved in space so the biped’s feet fall on the construction plane on the first frame of the clip. The letter Z appears after the clip name to indicate this setting.

When you load a clip into the Mixer for the first time, the clip name is followed by the number 1. If you clone or load the same clip to another part of the Mixer, the clip will display the same number or a different number depending on whether the new clip is an instance (page 3–958) or an adaptation (page 3–905) of the original clip. Instances are versions of the same clip used with the same object, or different objects of the same size. Adaptations are versions of the clip used with objects of different sizes.

The Mixer displays instanced clips with the same numbers, while adaptations receive sequential numbers. For example, if you clone a clip with the number 1 to a track for the same object, the new clip's name is also followed by the number 1. If you clone the clip to an object with a different size, the new clip is an adaptation, and the displayed name is followed by an incremental number: in this case, the number 2. If you then clone the adaptation to another track for the same object, the new clip is an instance of that clip, and will be displayed with the number 2. These numbers can help you determine which clips are instances of one another, and which are adaptations.

The ability to tell instances from adaptations becomes important when you replace a clip in the Mixer with another clip. During this operation, you have the option of replacing only the selected clip, only the instances of the clip, or all instances and adaptations of the clip.

Note: Operations in the Mixer, such as cloning clips and editing clip timing, do not affect the clip sources (BIP files).

**Procedures**

**To import BIP clips from a file:**

1. Select a biped, and open the Motion Mixer. See Adding Tracks to the Mixer (page 2–607).
2. In the Motion Mixer, highlight the track into which you want to bring the motion file. Be sure to highlight a blank area of the track and not any existing clips on the track.
3. From the Motion Mixer menu, choose Tracks > New Clips > From Files. You can also right-click the track and choose New Clips > From Files from the pop-up menu.
4. Navigate to the folder where your BIP files are stored, and select one or more BIP files. You can select as many BIP files as you like. These motions will be placed consecutively on the selected track.
5. Files imported into the Mixer in this way are automatically placed in the Reservoir.

**To import clips from the Reservoir:**

In order to import clips from the Reservoir, you must first place them in the Reservoir. See Using the Reservoir (page 2–626).

1. Highlight a blank area of the track into which you want to bring the motion(s).
2. From the Motion Mixer menu, choose Tracks > New Clips > From Reservoir. You can also right-click the track and choose New Clips > From Reservoir from the pop-up menu.
3. Select one or more BIP or XAF files.
To import clips from a motion flow script:
Motion flow scripts can be imported to a track in the Mixer. Both clips and transitions from the script are imported to the track.

Before you can import motion flow to a track, the biped must have at least one motion flow script assigned to it in Motion Flow mode. See Creating a Motion Flow Script (page 2–1030).

1. Highlight a blank area of the track into which you want to bring the Motion Flow clips and transitions. You can choose either a transition or layer track.
2. From the Motion Mixer menu, choose Tracks > Import Motion Flow. You can also right-click the track and choose Motion Flow from the pop-up menu.
3. Choose a script from which to import motion.
   The clips and transitions from the script are imported to the Mixer and displayed on the track. If the track was a layer track, it is converted to a transition track to accommodate the transitions imported from the script.

To see the motions in the Motion Mixer on the biped in the scene:
1. Select the biped for which you want to see the current motion from the Motion Mixer.
2. Click Mixer Mode on the Biped rollout.
3. Play the animation or drag the time slider to see the motion in viewports.

Working with Clips in the Mixer
Once you have created tracks and imported clips to the Motion Mixer, you can adjust your animation mix by moving, cloning, and replacing clips. Within the Motion Mixer, you can:
• Move clips in time within the same track.
• Move clips to other tracks.
• Clone clips.
• Slide all clips in time on a track.
• Replace a clip with motion from a biped, a motion flow script, or another clip.

To move a clip in time within a track:
1. Click Move Clips on the Motion Mixer toolbar.
2. Drag the clip and move it to another location on the track.
   A clip cannot be moved in such a way that it overlaps another clip. If you move a clip on top of another clip, it will return to its original location when you release the mouse.

Procedures
To move all clips horizontally on one track:
1. Select one or more clips. You can select multiple clips on different tracks for this operation.
2. Click Slide Clips on the Motion Mixer toolbar.
3. Move the selected clips to slide clips to the left or right.
   When you slide a selected clip to the right, all unselected clips to the right of the clip move to the right. When you slide a clip to the left, all unselected clips to the left move to the left.

To move a clip to another track:
1. Click Slide Clips on the Motion Mixer toolbar.
2. Move one clip on a track to slide all clips on the track.
To replace one clip with another:
After a clip is placed on a track, you can replace the clip with another clip. The new clip is scaled to fit the time of the original clip.

1. Select the clip(s) you want to replace.
2. Right-click a selected clip and choose Load Source > From Files from the pop-up menu. Select a BIP file to replace selected clips.
3. On the Mixer Clip Source Options dialog, choose whether to replace only the selected clips, or to also replace instances (page 3–958) (versions of the clip on same-sized bipeds) or adaptations (page 3–905) (versions of the clip on all bipeds).

To clone a clip:
Clips can be cloned within the same track, across tracks, and even across bipeds in the Mixer. A cloned clip retains the Z=0 status of the original clip (if this option was selected for the original clip), and any changes made to the original clip's timing. Cloning a clip to a different-sized biped creates an adaptation (page 3–905) of the original clip.

1. Make sure there's enough space on the track where you want to place the cloned clips. Move clips as necessary to make room.
2. Select the clip(s) you want to clone.
3. Hold down the [Shift] key on your keyboard, and drag the selected clips to the new location. If there isn't enough room where you attempted to place the cloned clips, the operations is cancelled and clips are not cloned.

To replace a clip with motion from a biped in the scene:
All motions used in the Motion Mixer must be saved as BIP files. When you copy animation from a biped in the scene, you must save this motion as a BIP file.

1. Place a clip in the track using any method.
2. Select the clips you want to replace with biped motion from the scene.
3. From the Motion Mixer menu, choose Clips > Load Source > From Biped. The Copy Biped Animation to Clip dialog (page 2–629) appears.
4. Highlight the biped from which you want to copy the animation.
5. Enter a filename for the new clip.
6. Click Copy to replace clips with the biped motion.

The name of the clip in the track is replaced with the new filename.

Filtering Mixer Tracks
Each track in the Motion Mixer is part of a trackgroup (page 3–1024). Each trackgroup can be filtered so it uses motions from one set of body parts and not another. For example, you might want to use the arm motions from one motion file with the legs from another. For this purpose, you would need two separate trackgroups.

There are two steps involved in filtering with trackgroups:
- Create additional trackgroups as needed in the Mixer.
- Filter each trackgroup (set it to use some body parts but not all), and name the trackgroup
appropriately. This is accomplished with the Trackgroup Filter dialogs (biped and non-biped objects).

When a trackgroup is created, it is given one Layer track by default. However, you can add more tracks to each trackgroup, making it possible to mix motions for each set of body parts. For example, you could create a trackgroup for the arms, and have two tracks within this trackgroup. Then you could put two completely different sets of motions on each track, and use weighting to use one track or the other at different times during the motion. See Adjusting Track Weight (page 2–619).
Chapter 12: Animation

Trackgroups for Spine, Legs and Arms. The Arms trackgroup has two tracks.

Note: Create only one trackgroup for each filtered set of body parts. For example, don’t use two trackgroups that both filter the spine. If you do so, the trackgroup highest in the Motion Mixer is used, and the other trackgroup is ignored. Instead, use multiple tracks within the trackgroup to achieve the animation you want.

Procedures

To add a new trackgroup for the biped:

1. Highlight the name of an existing trackgroup.
2. Right-click the trackgroup name and choose Add Trackgroup Above or Add Trackgroup Below.

A new trackgroup and Layer track are added above or below the existing trackgroups. You can add more tracks to the trackgroup by right-clicking the existing track and choosing one of the options from the pop-up menu.

To filter and name a trackgroup:

1. Highlight the trackgroup label at the upper left corner of the trackgroup you want to filter. By default, the trackgroup label is All, denoting that the trackgroup currently affects all biped parts.
2. From the Motion Mixer menu, choose Trackgroups > Filter.

The Trackgroup Filter dialog appears. By default, all body parts are selected.

3. Click on body parts in the diagram to select or deselect them. You can also use the buttons below the diagram to help make the selection. For example, if the trackgroup will affect only the arms, click None to deselect all biped parts, then click the four arm boxes to select the arms.

4. Enter an appropriate name for the trackgroup at the bottom of the Trackgroup Filter dialog, such as Arms.
5. Click OK to close the dialog.

The new trackgroup name appears at the upper left of the track display.

Adjusting Clip Timing

In the Motion Mixer, you can shorten clips or change their timing interactively within the track display. You can change the timing of motion clips in a number of ways:

- Change the length of a clip without changing its speed by trimming the clip at the start or end.
- Change the speed of an entire clip by stretching it out or shrinking it.
- Cause varying changes in speed throughout the clip with time warps. See Adding Time Warps (page 2–620).

Tip: When changing clip timing, it can be helpful to display start and end frame numbers and the clip time scale. To do this, click Preferences on the Motion Mixer and choose the appropriate options in the Mixer Preferences dialog (page 2–651). As you choose options, the Motion Mixer display is changed interactively.

Procedures

To change the length of a clip without changing its speed:

1. On the Motion Mixer toolbar, click Trim Clips.
2. Drag either end of a clip to trim its length.

A gray bar appears on a trimmed end of a motion clip.

3. Turn off Trim Clips.

The gray area disappears.

Tip: At any time, you can view original clip lengths in gray by turning on Trim Clips.
To remove scaling or trimming from a clip in the Motion Mixer, select the clip, right-click and choose Remove Scale/Trim.

**To change the speed of an entire clip:**
You can cause a motion to slow down or speed up by changing the length of the clip in the Mixer. Lengthening a clip will slow down the motion, while shortening the clip will speed it up.

1. On the Motion Mixer, click Move Clips.
2. Drag either end of the clip to extend or shorten it in time.

**Tip:** To see the ratio of the original motion time to the new time, click Preferences. In the Mixer Preferences dialog, turn on Scales. This displays the ratio on the clip next to its name.

---

**Working with Transitions**

When two or more clips are placed on a *transition track* (page 3–1027), you can create transitions between any two clips. A transition creates a constant, gradual change from one clip to another.

To learn how to create a transition track, see *Adding Tracks to the Mixer* (page 2–607).

If you want to make a less linear blend between clips than the blend created by a transition, see *Adjusting Track Weight* (page 2–619).

---

**Adjusting Transitions**

Transitions are automatically created between clips when you load the clips into a Transition track. You can adjust the start or end point of a transition by dragging either end of the transition in the Mixer.

When a transition appears with hatchmarks, this indicates that the transition is invalid. This can occur when a clip’s brackets are reversed, with the out-bracket before the in-bracket. You can correct this problem by dragging each end of the transition to reverse the ends.

A useful transition can occur anywhere where two clips overlap. The unused part of the clip on either side of the transition appears with hatchmarks to indicate that that part of the clip will not be used in the mix. This type of transition is often used for foot-based clips, when the best place for a transition is not always at the edge of a clip.

---

*Hatched parts of the clips are not used in the mix.*

The Motion Mixer will allow you to extend a transition into an area where two clips do not overlap. However, this transition will most likely result in undesirable motion in the mix.
Transitions extending into areas where clips don’t overlap can create unpredictable results.

For the best results, make sure all your transitions cover only areas where two clips overlap completely.

To aid in making your transitions as smooth as possible, you can select transitions and use the Transitions menu > Optimize option. This feature searches the two clips to find the start and end time that will result in the smoothest transition, and adjusts the transition accordingly.

If you want to snap the ends of a transition to the ends of clips, turn on Snap Clips on the Motion Mixer toolbar before dragging the transition edges.

When you move or scale a clip on a transition track, by default its transitions are also moved or scaled. To prevent transitions from changing when you move or scale a clip, turn on Lock Transitions on the Motion Mixer toolbar.

Using Transition Brackets

On a transition track, transition brackets appear around each transition, and at the start or end of each clip that is not surrounded by a transition.

Transition brackets

When you load a clip onto a transition track where clips already exist, the clip creates a transition between the last clip on the track and the new clip. The transition is created at the location of the last clip’s transition bracket.

You can move a transition bracket to create the transition automatically exactly where you want it before loading the next clip. This feature can make it very quick and easy to load a long series of clips into a transition track with correct transitions.

Working with Foot-Based Transitions

Much like Motion Flow, transitions in the Mixer between foot-based motion clips (clips where IK constraints keep the feet planted at various times) must be carefully placed and adjusted to make the animation look as natural as possible. The workflow depends on whether you are animating a biped, or 3ds Max objects such as a rigged character.

Foot-Based Transitions with Biped

For the most natural transitions between foot-based motions, follow this workflow:

1. Find a good place to start and end the transition.
2. Create the transition with this timing. You can also optimize the transition to fine-tune it.

3. Change the transition focus.

4. Perform a mixdown.

Study both clips to find a start time and range for the transition that will result in smooth motion. Look for times when each foot has the same planting or free status in both clips. For example, a time period when both clips have the left foot planted and the right foot free is a good time range for a transition.

You can fine-tune your choice of transition time by optimizing the transition. This feature searches each clip, either in its entirety or near an existing transition, to find the best timing for the transition.

You can improve a transition between foot-based clips by changing the transition focus on the Transition Editor dialog (Biped Object) (page 2–636). In the example described above, the left foot would be chosen as the transition focus, because this would keep the left foot planted while the animation moves around it.

When transitions cause a planted foot to slide or pop slightly, or force a leg to straighten unnaturally, you can use a mixdown (page 3–973) to correct these problems. See Exporting Animation to the Biped (page 2–624).

Foot-Based Transitions with 3ds Max Objects

For foot-based motions, follow this overall workflow:
1. Find a good place to start and end the transition.
2. Create the transition with this timing.
3. Choose the parent object to be a velocity blend object.
4. Choose the model's feet to be sub-blend objects.

5. Optimize the transition.

Procedures

To create a transition between two clips:

1. Right-click an existing track to insert a Transition track or convert the current track to a Transition track.
2. Right-click the track and choose New Clips > From Files from the pop-up menu. Choose at least two clips to load.
   - The clips are placed on the transition track with transitions between them.
3. Drag the transition to move it, or drag its ends to resize it.
4. Before adding the next clip, move the last clip's transition bracket to the next desired transition location, and then load the clip.

To optimize a transition:

With foot-based clips, you can use the Optimize command to help you find the best timing for a transition. The Optimize command exhaustively searches the specified time period for times when the foot positions match most closely.

Tip: A good workflow is to look at the clips individually to find the best approximate time for a transition, then use Optimize to fine-tune the timing.

1. Create a transition between clips at approximately the right location on the track.
2. Right-click the transition and choose Optimize from the pop-up menu.
   - The Transition Optimization dialog (page 2–641) appears.
3. Choose Search Near Existing Transition and click OK.

   The best transition is calculated, and the transition changes position and/or length in the Mixer to reflect the change.
Tip: If you aren’t sure where you want the transition to take place, you can choose Search Entire Clip. This option can place the transition anywhere in the two clips. Check the motion afterward to ensure the transition takes place at an appropriate time.

**To change the focus on a foot-based transition with Biped animation:**

1. Scrub the time slider to the middle of the transition.
2. Zoom in on the feet in any viewport.
3. Right-click the transition and choose Edit from the pop-up menu. Alternately, you can select the transition and choose Transitions > Edit from the Motion Mixer menu.

   The transition editor appears. In addition, two stick figures appear in viewports to show the bipeds’ positions in the two clips. The yellow stick figure shows the biped’s position in the first clip, while the red figure shows the second.
4. On the dialog that appears, choose a different Transition Focus from the list.

   As you change the Transition Focus, you will see the foot positions change. The Transition Focus sets a center or focal point for the transition, changing the biped’s position slightly depending on the setting. On foot-based transitions, try different settings to bring the yellow and red skeletons closer together on a planted foot.

   **Note:** Transitions involving planted feet often result in one or both feet sliding when they should stay planted. After setting up the transition, you can correct this problem with a mixdown. See *Exporting Animation to the Biped* (page 2–624).

---

**Adjusting Track Weight**

Each track has one or more weight curves (page 3–1033) that you can use to mix motion from several tracks to varying degrees. The weight curve determines how much a specific track contributes to the motion within the trackgroup.

With weight curves, you can create several full or partial transitions between all the tracks in a trackgroup. Compare with transitions on a transition track (page 3–1027), which can only create a full transition between two clips.

Weight curves are useful for:

- Creating transitions between two tracks in a trackgroup.
- Creating random motion.
- Experimenting with transitions quickly and easily.

Each track’s weight curve appears as a thin black line across the top of the track.

**Tip:** If you can’t see the weight curve, click Preferences to display the *Mixer Preferences dialog* (page 2–651). Turn Weight Curves off and on and watch the display to see the weight curve appear.

You access the weight curve by clicking the Weight Mode button at the right end of the track. Clicking Weight Mode on the Motion Mixer toolbar enables weight curve editing for all tracks. When Weight mode is on, you can work only with the weight curve, and not with clips.

You edit a weight curve using nodes (points) on the curve. Clips on layer tracks automatically have
a node at each end of each clip. A transition track has no nodes by default.

**Weight Curve Evaluation**

By default, each track’s weight curve is set to a value of 1.0 across the entire track, which uses 100% of the track’s motion in the mix. When you change the curve to dip to a value below 1.0, the motion on the track is mixed with the motion on the track below it. For example, if you set the weight curve for two tracks in a trackgroup to 0.5, the two clips will be mixed equally.

Several tracks can be stacked in a trackgroup with varying weight curves on each one. For each frame in the animation, the Motion Mixer evaluates the curve on the topmost track. If its weight curve is less than 1.0 at that frame, the Mixer evaluates the next track down, and so forth. The Motion Mixer adds up the weight curve values until the sum reaches 1.0, and disregards tracks below that point.

For Transition tracks, one weight curve is used for the entire track. On Layer tracks, weight curves are set individually for each clip.

**Procedure**

**To adjust a weight curve:**

1. Open the Mixer, add a biped to the Mixer, and create two tracks for a trackgroup. See Filtering Mixer Tracks (page 2–612).
2. Place different motion clips on the tracks.
3. **M** For the topmost track in the trackgroup, click Weight Mode to the right of the track display.
   
   The weight curve turns red to indicate it can be edited.
   
   You have to do the next two steps only if the weight curve has no nodes, or would like to create more nodes.
4. Move the cursor over the line until a small arrow appears. Click to set a node.
5. Move the cursor and click to set more nodes on the weight curve.

Tip: On a transition track, you would ordinarily set a node at each end of the track, and at intervals in between. The number of nodes you set depends on the type of curve you want to make. Make as few nodes as possible to get the curve required for your animation.

6. Move the cursor over an existing node until a cross cursor appears.
7. Click and drag to move the selected node downward.

The Motion Mixer mixes the motions from the topmost track with the track below it on that frame. The motions are mixed to a greater or lesser degree depending on how low you set the weight curve value for the topmost track.

### Adding Time Warps

Select a biped. > Motion panel > Biped Apps rollout > Mixer > Motion Mixer menu bar > Clips > Add Time Warp

You can cause varying changes in speed throughout a clip with a time warp. Adding a time warp to a clip allows you visually to squash and stretch time over different parts of the clip. You can use a time warp to:

- Cause the object to do some parts of the motion quickly and others slowly.
- Cause a particular motion within the clip to occur at a specific time.

You use a time warp by picking a time within the motion clip and dragging that time’s motion to another time in the same clip. The overall time of the clip is unchanged, so the object takes the same...
amount of time to do the entire motion, but does some parts quickly and others slowly.

Dashed lines appear on a time-warped clip in the Mixer to indicate the motion speed at different points in the clip.

Warping a clip’s time requires two steps. First a time warp must be added to the clip with the Clips > Add Time Warp menu option. Then you turn on Editable Time Warps to see the dashed lines and adjust the clip’s timing.

**Procedures**

**To prepare to warp a clip’s time:**

1. Open the Motion Mixer, add a biped to the Mixer, and load a clip on a track. See *Adding Tracks to the Mixer* (page 2–607).
2. Scrub the time slider to find a motion you would like to occur earlier or later in the clip. Note the frame number. This frame number is the original time.
3. Scrub the time slider to find the frame on which you would like the motion to occur, and note the frame number. This frame number is the warped time.

   With a time warp, you will cause the motion to occur at the desired frame by moving the original time to the warped time within the clip.

**To warp a clip’s time:**

1. In the Motion Mixer, zoom in on the original time for the time warp. This is the frame number you noted in step 2 of the previous procedure.
2. In the Motion Mixer, select the clip.
3. From the Motion Mixer menu, choose Clips > Add Time Warp.

   The appearance of the clip does not change when a time warp is added.
4. On the Motion Mixer toolbar, click Editable Time Warps.

   A series of evenly spaced dashes appears on the clip. The lengths of the dashes indicate the relative speed of the clip at various points. Right now, all dashes are evenly spaced to indicate the clip is playing at its original speed from beginning to end.
5. Move the cursor over the clip’s horizontal center line until an arrow cursor appears.
6. At the approximate original time, click the clip to set a time warp bar.
A time warp bar actually consists of two parts, a top and a bottom.

7. Click the top half of the bar. The top half turns white to indicate it is selected.

8. Drag the top half of the bar to the left or right to set it to the warped time noted in step 3 of the previous procedure. This will cause the motion at the original time to occur at the warped time.

Tip: As you drag the top bar, watch the Frame value at the top of the Motion Mixer window to see the top bar’s new frame number.

The lengths of the dashed lines change to indicate the new timing. Where lines are shorter, the motion will play faster. Where lines are longer, the motion will slow down.

9. Select and move the bottom bar to change the original time.

Either bar can be moved to change the effect of the time warp. The length of separation between the two bars sets the degree of time-warping that will occur. When both bars are aligned, no warping occurs.

To add multiple time warps to a clip:

1. You can time-warp other parts of the clip by adding more time-warp bars with the arrow cursor, then moving the new top bars. When you add a second time warp bar after editing the first, the top bar appears where you click, but the bottom bar appears in a different location. The bottom bar’s location corresponds to the original time of the top bar before the clip was time-warped.

Note: You cannot move one time warp’s top bar past another on the clip.

2. When you have finished warping the clip’s time, turn off Editable Time Warps.

When Editable Time Warps is turned off, the bars and the dashed line between them remain displayed on a clip to indicate it has been time-warped.

Adjusting Biped Balance in the Mixer

When you use different motions on the upper and lower parts of the biped, you can create a situation where the balance in the two clips do not match one another. For example, if the arms are waving wildly in the motion used for the upper body, the hip motion should compensate to some degree to keep the biped in balance. A straight mix of this arm motion with another hip/leg motion will most likely not match up in terms of balance.
Adjusting Biped Balance in the Mixer

Bipeds with same set of upper and lower body motions. Biped on the left has balance compensation, biped on the right does not.

By default, the Mixer compensates for differences in upper and lower body motion by making slight alterations to the spine and pelvis motions. If the biped bends over at the waist, for example, the pelvis will be moved to compensate for the weight shift, and the spine rotation will be lessened to help the biped keep its balance. Balance compensation is intended to make the biped’s motion look as natural as possible.

In the Mixer, you can control the degree of automatic balance compensation using the balance track. One balance track is automatically created for each biped as it is added to the Mixer.

The balance track has a weight curve for adjusting the degree of automatic balance compensation between upper and lower body trackgroups. By default, the weight value of 1.0 across the balance track provides the maximum degree of compensation. You can reduce the weight curve at various points to lessen the degree of automatic balancing performed by the Mixer.

Note: Each biped can have only one balance track, and the balance track cannot be deleted.

For fine adjustments to balance compensation, you can also change the parameters on the Balance Parameters dialog, available from the Mix menu.

Note: Balance Curves and related parameters are not available for non-biped mixes.

Procedures

To adjust balance using the balance track:

1. Add a biped to the Mixer, and create at least two trackgroups for the biped. See Filtering Mixer Tracks (page 2–612).
2. Filter one trackgroup to use motion only from the spine, arms and head. See Filtering Mixer Tracks (page 2–612). This trackgroup will hold the upper body motion.
3. Filter a different trackgroup to apply only to the legs, pelvis and COM tracks. This trackgroup will hold the lower body motion.
4. Add a clip with a great deal of upper body motion to the upper body track. See Importing Clips to the Mixer (page 2–609).
5. Add a clip with very different lower body motion to the lower body track.
6. Click the Balance Weight Mode button at the far right of the balance track.

Tip: If the balance track for a biped is not displayed, click Preferences on the Motion Mixer toolbar, and turn on Balance Curves on the Mixer Preferences dialog (page 2–651).
Chapter 12: Animation

The weight curve becomes visible at the top of the balance track.

Tip: If you can’t see the weight curve, click Preferences to display the Mixer Preferences dialog, and turn on Weight Curves.

7. Add nodes to the weight curve, and adjust the nodes. For information on how to add nodes and edit weight curves, see Adjusting Track Weight (page 2–619).

When the weight is set to 0.0, the Mixer will not adjust the spine and pelvis motion to compensate for differences in the upper and lower body motion. Values between 0.0 and 1.0 will adjust the balance to some degree.

To fine-tune balance compensation on the pelvis and spine:

The values on the Balance Parameters dialog can be used to make subtle adjustments to the biped’s balance.

1. In the Motion Mixer, select the biped by clicking its name at the upper left corner of its trackgroups.

2. From the Motion Mixer menu, choose Mix > Balance Parameters.

The Balance Parameters dialog appears.

3. To adjust the degree of horizontal balance compensation on the pelvis, change the Lateral Ratio parameter. Lower values make more forward/backward motion on the pelvis, while higher values use more side-to-side motion to compensate.

4. To adjust the degree to which spine rotation from the lower body motion is propagated on the upper body, change the Propagation parameter. Higher values rotate the spine links to better follow the COM and pelvis motion.

Exporting Animation to the Biped

Once you’ve worked with the Motion Mixer to create an animated sequence for the biped, there are several ways to work with the finished mix.

If you want to work with the mix on the current biped (rather than a another biped in the scene), you have several options:

• If you're satisfied with the animation as it is, you can turn on Mixer Mode on the Biped rollout (page 2–936) to display the mix on the biped, and simply render the scene.
If transitions between different foot/leg motions have created small pops or jerks near the transition area, you will want to create a mixdown (page 3–973) for the biped and check the mixdown before copying it to the biped. A mixdown can correct many continuity problems with feet and legs. You can correct transitions and recompute the mixdown as many times as you like. When the mixdown is satisfactory, you can copy it to the biped.

If you want to use the motion with a different biped, you can copy the mixdown to the current biped, save the motion as a BIP file, and load the new BIP file onto the other biped.

The mix can also be saved as a MIX (.mix) file. A MIX file (page 3–973) can be loaded onto other bipeds and edited as needed in the Motion Mixer.

**Fixing Foot-Based Transitions with a Mixdown**

When you create a transition between two motions with planted feet (feet with IK constraints), the motion might not match perfectly between clips. When this occurs, a planted foot might slide or pop, or a leg might stretch unnaturally during or near the transition period.

A mixdown can correct two types of problems during transitions between foot-based motions:

- A foot sliding as it transitions from one planted motion to another.
- A leg extending completely straight (hyper-extending) unnaturally to reach a planted position.

To have an effect on a mixdown, these options must be set before the mixdown is computed. If Prompt for options at each Mixdown is turned on, you will be prompted to set these options each time you compute a mixdown. Otherwise, the mixdown uses the settings on the Mixer Preferences dialog.

The options in the Mixdown Options group determine if and how the mixdown affects transitions between clips with planted feet. Enforce IK Constraints affects planted feet, while Filter Hyper-Extended Legs affects unnaturally straight legs. Turn on Prompt for options at each Mixdown if you want to be asked for these settings each time you do a mixdown. For more information on these options, see Mixdown Preferences Dialog (page 2–651).

**Procedures**

**To perform a mixdown and copy it to the biped:**

1. Select the biped in the Motion Mixer by clicking the biped name at the upper left of the trackgroup set.
2. From the Motion Mixer menu, choose Bipeds > Compute Mixdown.

If Prompt for options at each Mixdown is turned on in the Mixer Preferences dialog, you will be prompted for mixdown options. Click OK to start the mixdown.

A progress bar at the bottom of the Mixer shows the progress of the mixdown process. After a few moments, a new track called Mixdown is created as the last track in the biped’s mix. You can turn the track on and off by clicking the track. When the track is solid, the Mixdown track is on (active), and the biped performs the animation in the mixdown. When the track appears with hatchmarks, the track is off (inactive), and the biped performs the animation in the raw mix.

3. Click the Mixdown track to make it active.

4. Scrub the time slider or play the animation to check the transitions. If they need correction, turn off the Mixdown track, correct the transitions, and compute the Mixdown again. Repeat until the transitions are correct.

5. With the Mixdown track active, choose Bipeds menu > Copy Mixdown to Biped.

6. Turn off Mixer Mode if it is on.

The mix from the Motion Mixer is visible on the biped in viewports even though the biped is no longer in Mixer mode.

7. To save the animation as a BIP file, click Save File on the Biped rollout.

To save Motion Mixer data to a MIX file:

A MIX file saves the current state of the Motion Mixer data for a selected biped, including all clips, transitions, trims, scaling and time warps. It is not necessary to collapse clips before saving a MIX file.

1. Select the biped in the Motion Mixer by clicking the biped name at the upper left of the track set.

2. From the Motion Mixer menu, choose Bipeds menu > Save Mix File. Enter a filename for the .mix file, and click Save.

Using the Reservoir

The Reservoir serves as a storage facility for motion clips (page 3–975) (BIP and XAF files) that you use with the Motion Mixer. You can load clips directly into the Reservoir, and all clips that you load directly in the Motion Mixer also show up in the Reservoir.

For each motion file used in the Motion Mixer, the Reservoir list shows the source (disk path and name of the file), and, under the source, shows the name of each clip or set of clips derived from that file.

The Motion Mixer can apply multiple adaptations (page 3–905) (occurrences of the clip for different-sized bipeds) to different bipeds. In the Reservoir, the various clip adaptations are listed under the clip name.
If you click a clip in the list, the window under the list displays information about the clip, including structural differences between the figure it’s applied to and the figure from which the file was originally saved. A second window displays a graphical view of the biped animation; drag the slider below the window to move through the animation.

Note: The preview window is available only for BIP files.

Tip: For best results when loading animation clips that might require remapping into the Motion Mixer, load the clips directly into Mixer tracks, rather than going through the Reservoir. This always gives you the opportunity to remap the animation data.

Saving Clip Adaptations

The Reservoir lets you save a unique version of an adapted clip to a new BIP file. This new file will contain the new biped’s size data, so will not have to be adapted when it is loaded into the Mixer.

If you are mixing long BIP files on a biped of a size other than the size used to create the BIP file, when you reload the MAX file or load a MIX file, you might have to wait while the Mixer recalculate the adaptation for the biped. You can save loading time by saving adapted clips to new BIP files and replacing the original clip in the Mixer.

If you save an instanced clip from the Reservoir under a new file name, all clips in the Reservoir are renamed likewise.

Procedures

To access the Reservoir:

1. On the Motion Mixer toolbar, click the Reservoir button.
   The Reservoir opens.

To add clips to the Reservoir:

1. Choose between Max Clips and Biped Clips.

2. On the Reservoir toolbar, click the New Entry button.
   The Open dialog appears.

3. Find the directory containing the clip files to load, highlight the desired file or files, and then click the Open button.
   The file loads and appears as a Source in the Reservoir list. You can then add it to a track in the Motion Mixer using the latter’s New Clips > From Reservoir command.

To replace a clip in the Reservoir:

Use the Load File command to replace a highlighted source or clip.

1. In the Reservoir list, click a single item.
   The software permits replacing only one source or clip at a time.

2. On the toolbar, click Load File.
   The Open dialog appears.
3. Find the directory containing the clip files to load, highlight the desired file, and then click the Open button.
    The file loads and replaces the highlighted item in the Reservoir list and the Motion Mixer. If you replace a source item, all of its clips are replaced as well. If you replace a clip, all of its references are replaced.

To save an instanced clip to a new clip:
Once you apply a clip instance to a different biped in Motion Mixer, the software automatically fits the motion to the biped. You can then save the modified motion from the Reservoir.
1. In the Reservoir list, highlight the clip whose motion you want to save.
2. On the Reservoir toolbar, click the Save File button. Use the Save As dialog to specify a name and location for the motion file, and then click the Save button.
   The motion file is saved as fitted to the biped to which the clip is applied.
   Note: The motion file is saved at its original length, whether or not you changed the length of any instances of the clip in the Motion Mixer.

To save multiple instanced clips from the Reservoir:
1. On the Reservoir toolbar, click Batch Save.
   This operation does not depend on which items are highlighted in the Reservoir list.
2. In the Save Reservoir Items dialog, turn on items you want to save. For each source/clips group, you can save the source or any combination of clips, but not both.
   Optionally turn on Reset Names After Saving.
3. Click Save to save the specified items.

To remove clips not used in the Motion Mixer from the Reservoir:
If you delete all instances of a clip from the Motion Mixer, it appears in the Reservoir with a Refs value of 0.
- On the Reservoir toolbar, click Clean to remove these clips from the Reservoir.
   The motion file is saved under the new name.

Motion Mixer User Interface
Select a biped. > Motion panel > Biped Apps rollout > Mixer

Graph Editors menu > Motion Mixer...

The Motion Mixer is used to mix motion clips that are assigned to bipeds and non-biped objects. The concept of the Motion Mixer is based on audio mixing done in the music and sound industries. Like an audio mixer, Motion Mixer lets you add a series of tracks (page 3–1023) for each object in a scene. To each track you add clips (page 3–975) in the form of BIP or XAF files. You can also add transitions (page 3–1027) to smoothly link clips together. Clips and transitions can be filtered (page 3–939) so their motion affects only specified biped parts.

The entirety of the clips, transitions and other clip settings for a single object in the Motion Mixer is called a mix (page 3–972). As each object has its own mix, there can be several mixes in the Motion Mixer at any given time. You can save a mix as a MIX file (page 3–973).

For more information and procedures describing how to use the Motion Mixer, see Using the Motion Mixer (page 2–604) and the topics that follow it.
The Motion Mixer interface contains the following:

- The Motion Mixer menu bar (page 2–629), with five menus.
- The Motion Mixer toolbar (page 2–642), containing button-activated commands for adding bipeds, transitions, and other settings for creating a mix.
- The Motion Mixer editor (page 2–646), showing a graphical interface where the mix is built.

The Motion Mixer is normally opened as a floating window. It can also be opened in a viewport, like the Asset Browser and MAXScript Listener.

See also

Using the Motion Mixer (page 2–604)

Motion Mixer Menus

Select a biped. > Motion panel > Biped Apps rollout > Mixer

Graph Editors menu > Motion Mixer...

The Motion Mixer interface contains five menus located at the top of Motion Mixer window.

Interface

Mix menu
The Mix menu provides tools for managing your bipeds and non-biped objects when they are selected. If an object is already added to the Motion Mixer, right-clicking its name displays the menu. Use commands on this menu to load and save MIX files, adjust track colors and balance parameters, and activate and deactivate the Mixer mode.

Edit Max Mix Object—Opens the Edit Max Mix Object dialog, which lets you modify the content of the highlighted non-biped object mix. This dialog is comparable to the Max Objects To Mix dialog (page 2–642) with the exception of the Bake Removed Nodes option.

Note: This dialog is only available for non-biped object mixes.

Bake Removed Nodes—When on, animation keys from removed objects are baked to the main timeline. Default=off.

Add Trackgroup—Adds a trackgroup (page 3–1024) to the top of the selected object’s mixes.

Track Color...—Allows you to change the color of the clips in the selected object’s mixes. Choosing this command displays a Color Selector, where you can specify the clip color.

Balance Parameters...—Opens the Balance Parameters dialog. These values influence the effects of balance compensation on the biped’s
pelvis and spine when you use different motions on the upper and lower parts of the biped. See *Adjusting Biped Balance in the Mixer* (page 2–622).

Note: This dialog is available only for biped object mixes.

**Lateral Ratio**—Decreasing the Lateral Ratio to 0.0 will cause balance compensation to use only forward/backward motion on the pelvis. Increasing Lateral Ratio to 1.0 will adjust the pelvis with only side-to-side motion. Range=0.0 to 1.0; Default=0.5.

**Propagation**—Affects the degree to which spine links are rotated to follow COM and pelvis rotation. When set to 0.0 (the default), spine rotation is not influenced by lower body motion. When set to 1.0, all spine links except the topmost one use the lower body motion’s spine animation to some degree to better follow the COM and pelvis motion. The lowest spine link is rotated the most, and each subsequent spine link is rotated less and less. The topmost spine link is not rotated at all so arm motion will be preserved.

In order for this setting to affect spine rotation, the lower body motion must have some spine animation as part of the motion clip.

A Propagation setting above 0.0 is appropriate when the upper body motion causes the spine to bend over a great deal during a large part of the animation. Range=0.0 to 1.0; Default=0.0.

**Delete**—Clears the selected object(s) from the Mixer.

**Load Mix File**—Opens a dialog where you can select a MIX file (page 3–973) to load into the Mixer.

**Save Mix File**—Opens a dialog where you can save the current object’s mix (page 3–972) to a MIX file.

The following Mixdown-related tools are available only for biped object mixes.

**Compute Mixdown**—Performs a mixdown (page 3–973) on the selected biped(s). A Mixdown track appears at the bottom of each biped’s mix. Clicking the Mixdown track deactivates or activates it. When the Mixdown track is active, each biped inherits this single track’s animation rather than the transition and layer tracks in the mix. When the Mixdown track is inactive, the biped uses the raw mix (page 3–972) instead.

**Delete Mixdown**—Removes the mixdown from the mix of the selected biped(s).

The next three menu options are mutually exclusive; only one can be turned on at a time.

**Copy Mixdown to Biped**—Copies animation from the Mixdown track to the biped. The animation remains on the biped even after Mixer mode is turned off, and the animation can be saved as a BIP file.

**Effect Raw Mix**—When this option is turned on, Mixer mode is turned on for the biped. Default=active.
Effect Mixdown—When this option is turned on, the mixdown track is activated. This option is available only if a mixdown has been computed.

Effect Biped—When this option is turned on, Mixer mode is turned off for the biped. Click Effect Raw Mix to turn Mixer Mode on again.

Trackgroups menu
When a trackgroup is selected, you can access the commands in the Trackgroup menu. Alternately, you can right-click a trackgroup label to open the menu.

The Trackgroups menu lets you administer the bipeds in the mixer. Each biped you add to the Motion Mixer gets its own trackgroup, a selection of biped parts.

Filter...—Opens the Trackgroup Filter dialog where you can customize the object body parts that are included in a trackgroup mix. This command is only available when a single trackgroup is selected. For more information, see Trackgroup Filter Dialog (Non-Biped Object) (page 2–645), Trackgroup Filter Dialog (Biped Object) (page 2–645), or Filtering Mixer Tracks (page 2–612).

Add Trackgroup Above—Adds new trackgroups above the currently selected ones.

Add Trackgroup Below—Adds new trackgroups below the currently selected ones.

Add Layer Track—Adds a Layer track at the top of the selected trackgroups. Layer tracks hold clips to be mixed without transitions.

Add Transition Track—Adds a Transition track at the top of the selected trackgroups. Transition tracks hold clips that are mixed with transitions.
Clips in Transition tracks will automatically spawn transitions when they overlap.

Delete All Clips—Clears the selected trackgroups of all clips and transitions.
Delete—Clears the selected trackgroups from the Motion Mixer.

Tracks menu
The commands in the Tracks menu are only active when you have a track, or tracks, selected in the Mixer. These menu commands are also available when you right-click a track in the Mixer window.

Add Layer Track Above—Adds a new Layer track above the currently selected tracks.
Add Layer Track Below—Adds a new Layer track below the currently selected tracks.
Add Transition Track Above—Adds a new Transition track above the currently selected tracks.
Add Transition Track Below—Adds a new Transition track below the currently selected tracks.
Convert to Layer Track—Converts the selected Transition tracks to Layer tracks.
Convert to Transition Track—Converts the selected Layer tracks to Transition tracks.
Optimize All Transitions—All transitions on the track are optimized.

Clips menu
The Clips menu is active when a clip is selected or when you right-click a clip in the Mixer. Some menu commands are not available when multiple clips are selected.

Add Time Warp—Applies the ability to be time warped to the selected clips. A time warp allows you to alter clip speeds. It gives you the ability to stretch or squeeze time for parts of selected clips. For more details and procedures, see Adding Time Warps (page 2–620).

Optimize All Transitions—All transitions on the track are optimized.

New Clips > From Files—Opens a dialog where you can choose one or more BIP or XAF files to add to the selected track. If a selected BIP file has been saved for this release of 3ds Max, a thumbnail is displayed in the Motion Preview where you can move the slider and get an idea of what the motion looks like.

Any clip you add to a track using this method is automatically added to the Reservoir (page 2–649).

Note: If you choose a BIP file that is older, you will receive a warning that the file is obsolete and should be resaved. Until the BIP file is resaved, it will not display in the Motion Preview.

New Clips > From Reservoir—Opens a Reservoir Files dialog where you can choose one or more BIP or XAF files listed in the Reservoir.

Import Motion Flow—Allows you to import clips and transitions from a motion flow script to the selected track. You can import a script only if it is active on the currently selected biped, and if it has been loaded or saved as part of an MFE file (page 3–972). If scripts are available for import, the Motion Flow Scripts dialog displays a list of available scripts. The imported script replaces the currently selected track with a transition track (page 3–1027) containing all the clips and transitions in the script.

Note: This dialog is available only for biped object mixes.

Note: If the selected track contains clips and transitions when you choose this option, these clips are removed from the track when the motion flow script is imported.

Delete All Clips—Deletes all the clips residing on the selected track.
Delete—Deletes a selected track or tracks.
Motion Mixer Menus

Remove Time Warp—Removes the ability for clips to be Time Warped and removes any existing Time Warping from selected clips.

Tile View—Tiles the selected clip along the width of the Motion Mixer. The number of duplicated clips depends upon the clip’s length and the number of frames displayed across the Motion Mixer. For example, if a clip is 100 frames long and the number of frames across the Motion Mixer is 500, the clip will tile five times.

Tile Range—Tiles the selected clip along the range of the active time segment. The number of duplicated clips depends upon the clip’s length and the number of frames in the active time segment. For example, if a clip is 100 frames long and the number of frames in the active time segment is 500, then the clip will tile five times.

Remove Trim/Scale—Removes the trim/scale from the selected clip or clips.

Delete—Deletes a selected clip or clips from a track.

Load Source > From File—Opens a dialog where you can choose a new BIP or XAF file to replace selected clips. After selecting the new clip, the Mixer Clip Source Options dialog (page 2–634) is displayed.

Load Source > From Biped—Opens the Copy Biped Animation To Clip dialog (page 2–635), where you can choose a biped from which to copy animation to selected clips.

Load Source > From Reservoir—Opens the Reservoir File Groups dialog (page 2–635), where you can choose a clip from the Reservoir to replace selected clips.

Copy to Biped—Puts the clip’s animation onto the base state of the selected biped, evident when not in Mixer or any other mode. This option is available only when a single clip is selected.

Note: This dialog is available only for biped object mixes.

Collapse—Saves a collapsed version of the selected clip to a new BIP file. Collapsing removes all scaling, trims, and time warps from the clip, and prompts for a new BIP file name for the collapsed version of the clip. The original selected clip is replaced by the new clip. Collapsing a clip does not affect the selected clip itself.

Note: This dialog is available only for biped object mixes.

Transitions menu

Select a transition track to make commands on this menu active. Right-clicking a transition also opens this menu.

Edit—Opens either the Mixer Transition Editor dialog (Biped Object) (page 2–636) or the Mixer Transition Editor dialog (Non-Biped Object) (page 2–638), based on the kind of mix the transition is applied to. The dialogs are similar to the Transition Editor (page 2–1051) accessed from the Motion Flow rollout.

Optimize—Optimizes the selected transitions. This uses optimization algorithms similar to those in Motion Flow.

Convert To Loopable Clip—Allows you to create a loopable clip from a transition between two clips that are clones of one another. The two clips must share the same source file, meaning they must point to the same clip in the reservoir and they must have identical time warps and scales. Although the two clips don’t have to be created via cloning, it is probably the best way to create them.

The loopable clip will replace the two original clips and their transition and will begin exactly one frame before the transition starts, so at that frame, the animation will appear the same as it did.
before you created the loopable clip. If you tile the loopable clip after you create it, it should loop perfectly.

Note: This dialog is available only for biped object mixes.

Motion Mixer Dialogs

Mixer Clip Source Options Dialog

<table>
<thead>
<tr>
<th>Select a biped. &gt; Motion panel &gt; Biped Apps rollout &gt; Mixer &gt; Select clip(s). &gt; Motion Mixer menu bar &gt; Clips &gt; Load Source &gt; From File</th>
</tr>
</thead>
<tbody>
<tr>
<td>Select non-biped clip(s). &gt; Motion Mixer menu bar &gt; Clips &gt; Load Source &gt; From File</td>
</tr>
</tbody>
</table>

The Mixer Clip Source Options dialog opens when you select one or more clips on a track and choose Load Source > From File Clips menu (page 2–632). The new clip you choose replaces the selected clips. You also have the option of replacing instances (page 3–958) and adaptations (page 3–905) of selected clips.

Interface

Load Animation Into:
- The selected clips only—Replaces only the selected clip with the newly specified clip.
- All instances of the selected clip—Replaces instances of the clip (any occurrence of the selected clip within tracks for the same biped, or other bipeds of the same size).
- All instances and adaptations of the selected clip—Replaces adaptations (any occurrence of the selected clip on all bipeds’ tracks).

Method to Fit Animation to Clip:
- Scale animation to fit clip—Scales the length of the loaded clip to match the length of the clip it replaces in the track.
- Trim animation to fit clip—Trims the length of the loaded clip to match the length of the clip it replaces in the track.
- Set clip length to animation length, shifting remaining clips in time—For selected clips, changes the animation length to the loaded clip length. All clips on the track after the selected clip are shifted depending on the length of the newly loaded clip.
Remove Weights—Removes any existing weight curves from clips selected to be replaced.

Remove Warps—Removes any existing time warps from clips selected to be replaced.

Copy Biped Animation to Clip Dialog

Select a biped. > Motion panel > Biped Apps rollout > Mixer > Motion Mixer menu bar > Clips > Load Source > From Biped

The Copy Biped Animation To Clip dialog opens when you select one or more clips on a track and choose Load Source > From Biped on the Clips menu (page 2–632). The animation from the biped replaces the selected clips.

Note: This dialog is available only for biped object mixes.

Interface

Copy Animation Into:

- The selected clips only—Only the selected clip in the track is replaced by a new clip chosen from the reservoir.
- All instances—Replaces instances of the clip (any occurrence of the selected clip within tracks for the same biped, or other bipeds of the same size) with the clip selected from the Reservoir.
- All instances and adaptations—Replaces any occurrence (adaptation (page 3–905)) of the selected clip on all bipeds’ tracks in the Mixer, with the clip selected from the Reservoir.

Method to Fit Animation to Clip:

- Scale animation to fit clip—Scales the length of the loaded clip to match the length of the clip it replaces in the track.
- Trim animation to fit clip—Trims the length of the loaded clip to match the length of the clip it replaces in the track.
- Set clip length to animation length, shifting remaining clips in time—For selected clips, changes the animation length to the loaded clip length. All clips on the track after the selected clip are shifted depending on the length of the newly loaded clip.

Remove Weights—Removes any existing weight curves from clips selected to be replaced.

Remove Warps—Removes any existing time warps (page 2–620) from clips selected to be replaced.

Reservoir File Groups Dialog

Select a biped. > Motion panel > Biped Apps rollout > Mixer > Motion Mixer menu bar > Clips > Load Source > From Reservoir...

Graph Editors menu > Motion Mixer... > Select a non-biped object track > Motion Mixer menu bar > Clips > Load Source > From Reservoir...

The Reservoir File Groups dialog opens when you select clips and choose Load Source > From Reservoir on the Clips menu (page 2–632). This action replaces selected clips with the clip you choose from the Reservoir. This dialog shows a list of all the clips in the Reservoir (page 2–649).
Interface

Copy Animation Into:—

- **The selected clips only**—Only the selected clip in the track is replaced by a new clip chosen from the reservoir.
- **All instances**—Replaces instances (page 3–958) of the clip (any occurrence of the selected clip within tracks for the same object, or other objects of the same size) with the clip selected from the Reservoir.
- **All instances and adaptations**—Replaces any occurrence (adaptation (page 3–905)) of the selected clip on all objects' tracks in the Mixer, with the clip selected from the Reservoir.

Method to Fit Animation to Clip:—

- **Scale animation to fit clip**—Scales the length of the loaded clip to match the length of the clip it replaces in the track.
- **Trim animation to fit clip**—Trims the length of the loaded clip to match the length of the clip it replaces in the track.
- **Set clip length to animation length, shifting remaining clips in time**—For selected clips, changes the animation length to the loaded clip length. All clips on the track after the selected clip are shifted depending on the length of the newly loaded clip.

Remove Weights—Removes any existing weight curves from clips selected to be replaced.

Remove Warps—Removes any existing time warps from clips selected to be replaced.

Mixer Transition Editor Dialog (Biped Object)

The Mixer Transition Editor controls transitions (page 3–1027) on transition tracks (page 3–1027). When it is active, you view transitional stick figures to aid in placing your transitions. You can use this dialog to change the start and end times of transitions, change the transition focus, and perform other functions.

This dialog is very similar to the Motion Flow Transition Editor (page 2–1051).

Interface

Length—Sets the number of frames for the duration of the transition.

Transitions are calculated by matching velocities in both clips. Smooth out abrupt velocity changes using longer transitions.

Ease In—Ease-in value for the source clip.
Ease Out—Ease-out value for the destination clip.

Transition Focus—Lets you specify a focus point on the biped where the transition takes place. The Mixer will attempt to match movement based on this selection. For example, if Left Foot is selected, the transition will use the left foot as a focal point during the transition, aligning the motion of the left foot in both clips as much as possible during the transition. Default=Auto.

- Auto—The transition focus is calculated by averaging the overall position of the biped as it transitions from one clip to the next.
- Center Of Mass—The transition focus is based on the center of mass position of the biped as it transitions from one clip to the next.
- Left Foot—The transition focus is based on the left foot position of the biped as it transitions from one clip to the next.
- Right Foot—The transition focus is based on the right foot position of the biped as it transitions from one clip to the next.
- Both Feet—The transition focus is based on an averaged foot position of both of the biped’s feet as it transitions from one clip to the next.

Note: The best way to see the differences between the transition foci is by watching the yellow and red ghosts.

Preserve Height—When turned on, Preserve Height will allow gradual vertical motion to accumulate from the source to the destination clip. For example, climbing stairs will loop upward. If it is turned off, the next clip is always set so that its lowest point is at z=0. This default insures that motion does not gradually float up (or down) with each additional clip.

Angle—Sets the direction of the destination clip. The angle of the destination clip is automatically set for best body fit between the two clips when the Start Frame values change. Use Angle to change the direction of the destination clip.

Previous Transition—Go to the previous transition in the transition track.

Displays the previous transition in the Transition Editor, moves the time slider to the start frame of the previous transition and highlights the previous clip in the transition track.

Next Transition—Go to the next transition in the transition track.

Displays the next transition in the Transition Editor, moves the time slider to the start frame of the next transition and highlights the next clip in the Scripts list.

Optimize Transition—Displays the Transition Optimization dialog (page 2–641).

Options in the Transition Optimization dialog allow you to search for the location for the transition.

Go To Start Frame—Moves the time slider to the first frame of the transition.

The number field shows the start frame number.

Start Frame—Set the transition start frame for the source and destination clips in their respective fields. Duration for the source and destination clips displays above the Start Frame fields.

Rolling—Keeps the clip in motion during the transition.

Fixed—For the source clip, this option freezes the biped at the Start Frame position during the
transition. For the destination clip, this option freezes the biped at the End Frame position. If Fixes is chosen for both the source and destination clips, the transition is a gradual interpolation from one frozen pose to another.

**Set Start Frame**—Copies the value in the Frame field of the Ghost area to the Start Frame field in the Clip area. The position of the destination clip changes to match the biped body in the destination clip to the biped body in the source clip.

Locate an appropriate start frame for the source and destination clips by using the Frame spinner and viewing the positions of both stick figures, then click Set Start Frame.

The destination clip is rotated and positioned to match both bipeds. Use the Angle spinner to reorient the destination clip.

**Frame**—Use the Frame spinner to scrub a stick figure back and forth, which allows you to determine a start frame for the source and destination clips. Visual feedback of the stick figures is a good way to judge which start frames are needed for the source and destination clips.

---

**Mixer Transition Editor Dialog (Non-Biped Object)**

The Mixer Transition Editor controls transitions (page 3–1027) on transition tracks (page 3–1027). You can use this dialog to change the start and end times of transitions, change the transition focus, and perform other functions. Mix transition blend objects are changeable from clip to clip, and any new transition that results from cloning or adding clips initially uses the blend options from the last clip in time.

The options on this dialog are much the same as for Bipeds, except that:

- Mix transitions for 3ds Max objects do not have ghosting or playback controls.
- You can explicitly pick blend objects from any object being mixed in the track.
- The sub-blend capability provides further tuning of the transition.

**Blending and Sub-Blending**

Consider a character walking around a corner. The trajectory of the character’s root describes an arc, while the IK feet cycle along the ground. This clip contains a few footsteps, and is used to make a mixer cycle that should take the character around in a circle. If you set the root and the feet all to be velocity blends, the transition will result in the root continuing around the corner while the feet continue in whatever direction they were moving at transition time! That is, if the right foot was just about to hit the ground with its heel, thus pointing up a bit, it would transition upward into the next clip instead of blending in the direction that the root’s arc is taking. If you set the root to be a velocity blend and then set the feet to be sub-blends of the root, the transition results in the root continuing on its arc around the corner but with the feet blending in relation to it. That is, the upward-pointing right foot motion will blend with the foot motion in the new clip but in the direction of the arc, not in its own upward direction.
Interface

Mixer Transition Editor Dialog (Non-Biped Object)

Length—Sets the number of frames for the duration of the transition. Transitions are calculated by matching velocities in both clips. Smooth out abrupt velocity changes using longer transitions.

Ease In—Ease-in value for the source clip.

Ease Out—Ease-out value for the destination clip.

Source Clip and Destination Clip groups

The following options let you set different parameters proper to both source and destination clips involved in the transition.

Start Frame—Set the transition start frame for the source and destination clips in their respective fields. Duration for the source and destination clips displays above the Start Frame fields.

- Rolling—Keeps the clip in motion during the transition.
- Fixed—For the source clip, this option freezes motion at the Start Frame position during the transition. For the destination clip, this option freezes motion at the End Frame position.

If Fixed is chosen for both the source and destination clips, the transition is a gradual interpolation from one frozen pose to another.

Velocity Blends group

A Velocity Blend object is one that has its positions blended based on velocity (like a biped’s COM). Objects used for Velocity Blending are most commonly the roots of the mix hierarchy. When you pick an object for velocity blending, its animation will accumulate based on its trajectory in the scene; for example, choosing the root of a character as the blend object will ensure that the character’s animation is transitioned relatively from clip to clip, so the character keeps moving through world space instead of repeating each clip as absolute. All children of the root will follow in the transition.

In some cases, you might want to use velocity blending for a child object.

By default, the Transition Editor uses no velocity blend objects.

Important: If you use velocity blending, pick your blend objects before you optimize the transition.

Velocity Nodes list—Lists the objects you have chosen for velocity blending.

- Select Velocity Nodes—Click to display a Pick Nodes dialog (page 2–641) and choose the objects to velocity blend.
- Delete Velocity Nodes—Click to delete the highlighted objects from the list.
- Set Other Transition Velocity Nodes—Copies the set of velocity blend objects to all other transitions in the current track.

Roll—When on, accumulates the roll (X) angle during the transition. When off, the angle is simply blended with the next clip. Default=on.
The spinner value lets you specify an additional angle to add to the roll.

**Pitch**—When on, accumulates the pitch (Y) angle during the transition. When off, the angle is simply blended with the next clip. Default=on.

The spinner value lets you specify an additional angle to add to the pitch.

**Yaw**—When on, accumulates the yaw (Z) angle during the transition. When off, the angle is simply blended with the next clip. Default=on.

The spinner value lets you specify an additional angle to add to the yaw.

**X/Y/Z**—When on, accumulates position in the specified axis during the transition. When off, the position is simply blended with the next clip. Default=on.

**Sub-Blends group**

In order for other world-space objects to transition within the space of the velocity blend or a child of the velocity blend, you need to specify a sub-blend. For example, think of a rig that has a root moving through world space, and also has world-space IK foot controls. In this case, you would pick the root as the velocity blend, then select the root in the list and add the foot controls as its sub-blends. The result of this will be the that root makes a smooth transition and the feet make a smooth a transition as possible in the direction that the legs are going (within the root’s space) at transition time, not in the direction that the feet themselves are going at transition time.

**Sub-Blend Nodes list**—Displays the objects chosen for sub-blending.

Before you pick sub-blend nodes, you must first choose a velocity blend node in the upper list. Typically this is the parent of the nodes that will be sub-blends.

- **Delete Velocity Nodes**—Click to delete the highlighted objects from the list.

- **Set Other Transition Velocity Nodes**—Copies the set of velocity sub-blend objects to all other transitions in the current track.

Before you pick sub-blend nodes, you must first choose a velocity blend node in the upper list. Typically this is the parent of the nodes that will be sub-blends.

- **Previous Transition**—Goes to the previous transition in the transition track.

  Displays the previous transition in the Transition Editor, moves the time slider to the start frame of the previous transition and highlights the previous clip in the transition track.

- **Next Transition**—Goes to the next transition in the transition track.

  Displays the next transition in the Transition Editor, moves the time slider to the start frame of the next transition and highlights the next clip in the Scripts list.

**Current Frame**—Displays the current frame number.

- **Go To Start Frame**—Moves the time slider to the first frame of the transition.

- **Optimize Transition**—Displays the Transition Optimization dialog (page 2–641).

  Options in the Transition Optimization dialog allow you to search for the location for the transition.

**Important:** If you use velocity blending, pick your blend objects before you optimize the transition.
OK—Confirms the current settings and closes the dialog.

### Pick Nodes Dialog (Motion Mixer)

**Graph Editors menu** > Motion Mixer... > Select a non-biped object clip transition. > Motion Mixer menu bar > Transitions > Edit > Mixer Transition Editor > Click one of the Select Velocity Nodes buttons.

This dialog appears when you pick nodes for velocity blending or sub-blending. If you click the Select Velocity Nodes button associated with the Velocity Blends list, the list displays only the objects being mixed in the current transition track. If you click the Select Velocity Nodes button associated with the Sub-Blends list, the list displays only the objects being mixed in the current transition track, except those objects that are already velocity blends.

### Interface

**Search field**—To find an object in the list, enter the object’s name and then press Enter.

**Node list**—Lists all the available objects.

**All**—Selects all objects in the list.

**None**—Selects no objects in the list.

**Invert**—Inverts the current list selection.

**Subtree group**

**Display**—When on, the object hierarchy is shown by indenting. When off, all objects appear at the same level. Default=on.

**Select**—When on, selecting an object selects that object’s children. When off, only one object at a time is selected. Default=off.

**Named selection sets drop-down list**—This list shows the scene’s named selection sets (page 1–83). Choosing a set from this list selects its members in the Node list.

### Transition Optimization Dialog

**Motion Mixer** > Create a transition track. > Place clips on the track. > Right-click the transition. > Optimize > Transition Optimization dialog

**Motion Mixer** > Create a transition track. > Place clips on the track. > Select the transition. > Transitions menu > Optimize > Transition Optimization dialog

Options in the Transition Optimization dialog allow you to select the range over which the optimize algorithm will search for a transition. It can search either the whole clip, or it can search near the existing transition. You must specify the preferred length of the optimized transition. The software will try to get as close to that length as possible, still opting to give you the best length.

If it searches about the existing transition, you must specify the number of frames about which it will search before and after the existing transition.
Optimized transitions compute for minimum foot sliding over the range of the transition. This method of determining transitions yields very high quality results.

**Interface**

- **Preferred Transition Length**—Specify the preferred length of the optimized transition.
- **Search Entire Clip**—Search the entire clip for an optimized transition start frame.
- **Search Near Existing Transition**—Allows animators to find good transitions that "are in the ballpark" of their existing transitions. Transitions can be fine tuned without drastically changing the animation's timing. In general, there may be several "good transitions", so this feature narrows the range of search to the ones that are near to the current settings.
- **Search Range about Existing Transition**—Allows animators to set a “before” and “after” range of frames to perform a search for other transitions that are close to the selected transition. Both ranges default to 20 frames around the selected transition.
- **Before**—Set a frame value to search before the existing transition.
- **After**—Set a frame value to search after the existing transition.

**Motion Mixer Toolbar**

Select a biped. > Motion panel > Biped Apps rollout > Mixer

Graph Editors menu > Motion Mixer...

Like an audio mixer where you add music tracks and use fades and blends to transition between tracks, the Motion Mixer allows you to mix motion clips. The Motion Mixer toolbar offers commands that you use to add and delete biped and non-biped objects to and from the mixer, modify clips, and change the way tracks in the mixer are displayed.

**Interface**

- **Add Max Objects**—Opens the Max Objects To Mix dialog, which lists all non-biped objects in the scene. This dialog lets you add objects to be driven by your mixed animation, as well as name the mix in which they are contained.

This dialog is comparable to the Select Objects dialog (page 1–78).

**Note:** The default mix name is the root node with the most children in the list.

**Note:** Objects can be added to only one mix at a time. Once an object is part of a mix, it is removed from the list.
Add Biped—Opens the Bipeds dialog listing all the bipeds in the scene. Highlight one or several bipeds to load them into the Motion Mixer window.

Tip: You can click-drag over all, or several adjacent bipeds in the list if you want to add multiple bipeds to the Motion Mixer. If the bipeds you want to add are not next to one another, hold down the [Ctrl] key while choosing the bipeds you want to add.

Delete—Deletes a selected biped from the Motion Mixer window.

Select—Lets you select bipeds, trackgroups, tracks, and clips.

Move Clips—Allows selection and movement (including [Shift]+Clone) of bipeds and trackgroups, keeping clips and transitions intact. It also allows independent horizontal movement of clips on the same track or vertical movement of clips from one biped’s track to another biped’s track.

Slide Clips—Allows horizontal movement of clips on the same track or vertical movement of clips from one biped’s track to another biped’s track. Sliding a clip to the right will move unselected clips which are situated to the right of the selected clip; sliding to the left will move unselected clips which sit to the left of the clip.

Offset—Records how many frames have been displaced. This value appears in the status area next to Slide Clips only during interactive translations, such as moving a clip or editing a time warp. The Offset value resets to zero when the translation is complete.

Frame—Displays the frame number under the cursor during interactive translations, such as stretching a clip or editing a time warp. When stretching a clip, you can use both the Frame and Offset fields to tell you how many more or fewer frames the clip will have.

Trim Clips—Clips can be trimmed from their original lengths interactively. When using this mode, you can grab the edge of a clip and drag it to a new frame within the clip’s original length. This mode will display all trimmed portions of clips in the Motion Mixer as gray. See Adjusting Clip Timing (page 2–615).
Editable Time Warps—Clips can be interactively time warped, given that they have had a warping applied. When in this mode, you can place seams in a clip and then drag them within the clip’s original length. See Adding Time Warps (page 2–620).

Draggable Tracks—Enables vertical movement of tracks with clips. Holding down the Shift key while moving a track creates a clone of the original track.

Lock Transitions—When Lock Transitions is turned off (the default), moving a clip or changing its length on a transition track affect the lengths of transitions around the clip. When Lock Transitions is turned on, transition lengths do not change when you move a clip or drag clip edges not touching the transition. You can still change a transition’s length by dragging the edges of the transition itself.

Set Range—Matches the active segment’s start and end times to the extents of the mix.

Pan—Pans the Motion Mixer display horizontally and vertically.

Zoom Extents—Stretches or shrinks the mix to fit in the current Motion Mixer display.

Zoom—Allows horizontal stretching and shrinking of the display of the mix.

Zoom Region—Zoom into a portion of a track by dragging a region selection around that part of a track.

Snap Frames—An on/off toggle that sets the Motion Mixer to snap all adjustments to single frames.

Snap Clips—An on/off toggle that causes clips residing on the same track to snap together. The end frame of one clip will match the start frame of the next clip. If the first clip ends at frame 100, the start frame of the next clip will snap to frame 100. When Snap Clips is on, transition edges snap to clip edges when dragged.

Preferences—Opens the Mixer Preferences dialog (page 2–651), where you can change display settings for clips, transitions, and frames.

Reservoir—Opens the Reservoir dialog (page 2–649).

Horizontal—This button is available when the Weighting button on the motion mixer toolbar or on a trackgroup is active. It locks all movement of weight nodes to the horizontal.

Vertical—This button is available when the Weighting button on the motion mixer toolbar or on a trackgroup is active. It locks all movement of weight nodes to the vertical.

Horizontal Vertical—This button is available when the Weighting button on the motion mixer toolbar or on a trackgroup is active. It allows free horizontal and vertical movements of weight nodes.

Weight Mode—An on/off toggle that allows you to work with weight curves. Weight curves are useful for making smooth blends between tracks. The Weight Mode button on the Motion Mixer toolbar acts as a global switch that toggles the Weight Mode buttons on every track in the Mixer. The Weight Mode button at the right end of each track toggles weighting only for that track. For more information on how weight curves work, see Motion Mixer Editor (page 2–646). To find out how to use weight curves, see Adjusting Track Weight (page 2–619).

*Adding Tracks to the Mixer (page 2–607)*

*Using the Reservoir (page 2–626)*

**Trackgroup Filter Dialog (Biped Object)**

Select a biped. > Motion panel > Biped Apps rollout > Mixer > Trackgroups menu > Filter

By default, the Motion Mixer expects that a mix you create will affect the entire biped. If you like, you can filter (page 2–612) a trackgroup so clips in the mix affect only selected body parts. This functionality makes it easy for you to assign one set of BIP files to control the motion of a biped’s upper body, while another set controls the lower body.

For more information and procedures on the use of trackgroup filters, see *Filtering Mixer Tracks (page 2–612)*.

**Interface**

The Trackgroup Filter dialog consists of a rough diagram of a biped. Selectable components display in the color specified for the trackgroup by the Track Color command on the Mix menu (page 2–629). If the biped does not include parts like ponytails or props, they are unselectable. Body parts can be individually activated or deactivated by clicking them, or you can use the buttons across the bottom of the Trackgroup Filter diagram to expedite selections.

**Center**—Activates all central body parts, comprised of the spine, pelvis and horizontal movement, rotation and vertical movement icons.

**Arms**—Activates the biped’s arms, comprised of the right arm, left arm, and both hand icons.

**Legs**—Activates the biped’s legs, comprised of the right leg, left leg, and both foot icons.

**All**—Activates all selectable body parts.

**None**—Deactivates all body parts.

**Invert**—Inverts the current body part selection. If everything is active, this deactivates everything, as if you clicked the None button.

**Trackgroup Label Field**—Use this field to specify a more descriptive label for a trackgroup. When you first create a trackgroup, it is labelled All. The new label entered here will appear in place of All to the left of the trackgroup. Use a unique, descriptive name to help you keep track of what body parts were filtered for the trackgroup. For example, if you selected only the pelvis and legs, you could enter *Lower Body* as the trackgroup label.

**Trackgroup Filter Dialog (Non-Biped Object)**

Graph Editors menu > Motion Mixer... > Trackgroups menu > Filter

By default, the Motion Mixer expects that a mix you create will affect the entire non-biped object. If you like, you can filter (page 2–612) a trackgroup so clips in the mix affect only selected body parts. This functionality makes it easy for you to assign one set of XAF files to control the motion of an
object’s upper body, while another set controls the lower body.

For more information and procedures on the use of trackgroup filters, see *Filtering Mixer Tracks* (page 2–612).

**Interface**

**Search field**—To find an object in the list, enter the object’s name and then press **Enter**.

**Object list**—The Trackgroup Filter dialog displays a list of objects, with the hierarchy indicated by indenting (if Subtree > Display is on, which it is by default). Objects can be individually activated or deactivated by clicking them, or you can use the buttons across the bottom of the Trackgroup Filter diagram to expedite selections.

**All**—Activates all selectable

**None**—Deactivates all body parts.

**Invert**—Inverts the current body part selection. If everything is active, this deactivates everything, as if you clicked the None button.

**Subtree group**

**Display**—When on, all body parts are listed following a hierarchy structure. Otherwise, body parts are listed on the same level. Default=on.

**Select**—When on, highlighting a body part automatically select all its children.

**Named selection sets drop-down list**—This list shows the scene’s named selection sets (page 1–83). Choosing a set from this list selects its members in the Object list.

**OK**—Confirms selection and closes the dialog.

**Cancel**—Disregards current selection and closes the dialog.

**Motion Mixer Editor**

Select a biped. > Motion panel > Biped Apps rollout > Mixer

The Motion Mixer window contains an editor where you manage everything that is added to the mix: bipeds, trackgroups, tracks, clips, and transitions.

**Interface**

The editor contains three sections:
• Biped/Trackgroup/Track Controls (page 2–647)
• Interactive Clip Controls (page 2–647)
• Weighting Controls (page 2–648)

Biped/Trackgroup/Track Controls

The left-most section of the editor is the Biped/Trackgroup/Track Controls section. The Biped/Trackgroup/Track Controls set the number, order, display, and characteristics of those features in the mix. Bipeds and trackgroups can be selected, added, removed and repositioned.

The “-” and “+” buttons collapse and expand the display of bipeds and trackgroups. The “m” button mutes a track, taking its influence out of the mix. The “s” button sets a track to solo mode, making it the only active track in the mix.

Interactive Clip Controls

The center section of the editor, Interactive Clip Controls, lets you manipulate the scale, time, timing, and trimming of clips and transitions.

The overall length of all clips and transitions in a track can be stretched or squeezed by dragging the white ends of the gray range bars along the top of each trackgroup. Drag from the middle of the range bar if the entire mix of a trackgroup needs to be moved. Likewise, clips can be moved by dragging from the middle of a clip. Clips and transitions can be shortened or lengthened by dragging either end.

The range bar for each biped can also be moved or scaled to move or scale the entire mix for the biped.

Transition brackets appear in Transition tracks. Where a transition exists, the brackets indicate the start and end point of the transition. If there is no transition at the end of the clip, the bracket indicates where the transition will be placed when a new clip is loaded into the track.

The current time in the scene can be changed by dragging the vertical, purple timeline, a change which is reflected on the 3ds Max time slider.
Chapter 12: Animation

The vertical timeline.

If a clip has a time warp applied, time can be distorted interactively in Time Warp mode: first create seams in the clip, then drag the seams to stretch or squeeze time.

Note the corresponding changes in the frequency of the time ticks down the center of the clip. Time warps are used to speed up or slow down a motion.

Weighting Controls

The weighting controls at the rightmost end of the editor let you set the weight with which a clip or track will be blended with other tracks within the same trackgroup.

On a Layer track, each clip has its own weight curve. Each Transition track has one weight curve for the entire track. By default, each weight curve has a node at each end that can be moved to change the weight at that point. Click on the weight curve to add more nodes, and drag a node to move it.

Weights can range from 0.0 (no weight) to 1.0 (full weight). The weight for the currently selected node appears to the left of the Weight Mode button. You can change the weight by moving the node or by changing the spinner value.

When you have multiple weight nodes selected, and you use the spinner to set a new value, weight node values are changed relative to their original values. In this case, you cannot spin the spinner lower than 0 or higher than 1 on any one spin. If you have more than one weight node selected and
you type in a weight, the weights of all nodes are changed to the new value.

Weighting is evaluated across tracks in a single trackgroup. If a trackgroup has two or more tracks, the topmost track’s weight is evaluated at each frame. If the weight at any frame is less than 1.0, the motion on the track is only partially used, and next track down is evaluated for its weight. If the total weight is still less than 1.0, the next track down is evaluated, and so on. In this way, motion from multiple tracks can be mixed at the same frame for the same set of body parts.

The Weight Mode button at the right end of the main toolbar turns on this mode for all tracks in the Motion Mixer. For more information, see Motion Mixer Toolbar (page 2–642).

In a balance track, the Balance Weight Mode button appears rather than the Weight Mode button. When in Balance Weight mode, you can adjust the weight curve for the balance track (page 3–914). To find out how to use Balance Weight mode, see Adjusting Biped Balance in the Mixer (page 2–622).

The Reservoir comprises four parts:

- The Reservoir toolbar (page 2–650), where all the commands are located. You can choose between listing biped clips and non-biped clips.
- The Source/Clipname list (page 2–650), where motion clips (BIP and XAF files) are listed. Instances (page 3–958) are grouped together in one listing, while adaptations (page 3–905) are listed separately.
- The Clip Status field (page 2–650), where you can gather information about the clips used in the Motion Mixer.
- The Motion Preview (page 2–651), where you can see what a motion looks like before you use it.

Note: The Motion Preview is available only when you choose the Biped Clips option.
Reservoir toolbar

The commands on the main Reservoir toolbar allow you to manage the clips you have in the Motion Mixer and also build up a collection of clips that you may want to use in the future.

Max Clips/Biped Clips—Choose to switch between a list of biped and non-biped motion assets. The Max Clips option displays XAF files while Biped Clips displays BIP files.

New Entry—Opens a dialog where you can choose BIP or XAF files to load into the Reservoir. You can highlight multiple files to load by holding down the [Ctrl] key while you click.

Reload Files—Reloads selected BIP or XAF files listed in the Reservoir.

Load File—Opens a dialog where you can choose a new BIP or XAF file to replace the selected entry.

Save File—Allows you to save a highlighted clip from the Reservoir. The Save As dialog is displayed and you can specify a name and location for the clip you are saving.

Batch Save—Opens the Save Reservoir Items dialog, where you can choose the clip or clips to save.

Delete—Removes a highlighted clip from the Reservoir. All instances of the clip are also removed from the Motion Mixer.

Clean—Similar to Delete, but only removes clips from the Reservoir that are not used in the Motion Mixer.

Auto Clip Names—Names the clip based on the name of the motion file. Turn off to name a clip yourself.

Source / Clipname list

The Source / Clipname List displays all the clips you have in the Motion Mixer Reservoir. Four pieces of important information can be gathered from this list:

- Drive location where the clips are stored.
- Which clips are currently being used in a mix.
- How many times each instance of a clip appears in the Mixer (Refs).
- Which clips are simply being held in the reservoir, as opposed to being used in the Mixer.

As you add clips to a track, from the Tracks menu (page 2–632) or by right-clicking a track, they are automatically added to the Reservoir. If the clip is a new adaptation (page 3–905), the name of the clip is assigned an incremental suffix, such as 1 or 2.

The Refs (Reference) column tells you how many times a clip instance (page 3–958) has been used in the Motion Mixer, or if it has not been used at all. If an instance shows a Refs value of 1 or more, it means the instance has been used that many times. If an instance shows a Refs value of zero, it means the clip was once used by one or more bipeds, but is not currently used on any tracks.

If a clip has been added to the reservoir, but has never been placed in the Motion Mixer, only the source path will be listed and no Refs value is displayed.

Clip Status field

The Clip Status field appears at the lower left of the Reservoir and gives you information about how a particular clip has been used. You can get file information, such as the source location of the BIP
or XAF file. Clip information is also displayed, like the name of the clip reference as it appears in the Motion Mixer. Information about the biped structure is also listed along with the bipeds to which the clip has been adapted.

Motion Preview

The Motion Preview at the lower right side of the Reservoir shows a thumbnail of the selected clip. Moving the slider across the bottom gives you an idea of what the motion looks like before you add it to a track.

Note: In order for a clip to show in the Motion Preview, it must be a BIP file that has been saved for this version of 3ds Max. If you choose a BIP file that is from an older version of 3ds Max, you will see a warning that the file is obsolete and should be resaved. Until the BIP file is resaved, it will not display in the Motion Preview.

Note: The Motion Preview is available only when you choose the Biped Clips option.

See also

Using the Reservoir (page 2–626)

Mixer Preferences Dialog

Select a biped. > Motion panel > Biped Apps rollout > Mixer > Preferences
Graph Editors menu > Motion Mixer... > Preferences

The Motion Mixer Preferences dialog lets you make changes to display settings for clips, transitions and frames. It is similar to the way you can Hide By Category on the Display panel. You can also specify mixdown options from this dialog.

The settings on the Motion Mixer Preference dialog are saved in the biped.ini file, as well as with the MAX file.

Interface

Show / Hide group

These settings affect how clips appear in the Motion Mixer tracks.

- **Names**—When turned off, clip names do not appear on the colored clip bars in the Motion Mixer. Default=On.
- **Scales**—Displays the clip scale. Since clips can be resized by using tools like Move Clips, displaying the scales quickly lets you know if a clip is two times its original length or half its length. Default=Off.
- **Boundaries**—Turns on and off the frame numbers at the start and end of the colored clip bars. Default=On.
- **Weight Curves**—Toggles the display of the weighting line. It doesn’t matter if the Weight button is active or not. Default=On.
- **Time Warps**—If a time warp has been added to a clip, this switch toggles the display of the warp on the colored clip bar. Default=On.

Show / Hide Transitions group

The two settings affect how transitions appear in the Motion Mixer tracks.

- **Inpoints**—Toggles the beginning transition frame on the transition clip bar. Default=On.
• **Outpoints**—Displays the end transition frame on the transition clip bar. Default=Off.

**Show / Hide Other group**
These settings indicate if range bars and balance curves appear in the Motion Mixer tracks.

• **Trackgroup Rangebars**—Hides the gray range bar that appears along the top of each trackgroup. Default=On.

• **Balance Curves**—Displays the Balance Curves track. Default=On.

**Frame Display group**
These settings affect how clip boundaries and transition in/outpoints appear in the Motion Mixer.

• **Global**—Displays clip start and end frames as frame numbers. Inpoints and outpoints of transitions display the frame at which transitions start and end. Default=On.

• **Local**—Clip boundary values are displayed as actual lengths in frames. Along with the start and end frame number of the transition, additional values tell you by how much the transition overlaps each motion clip.

**Mixdown Options group**
These settings affect how transitions between biped object clips appear in the Motion Mixer tracks.

• **Prompt For Options At Each Mixdown**—When turned on, the Mixdown Options dialog is displayed when you choose Compute Mixdown from the Mix menu in the Motion Mixer. Default=On.

• **A Keyframe Per Frame**—When turned on, a keyframe is generated for each frame of animation when the mixdown is computed. Default=Off.

• **Enforce IK Constraints**—When a transition occurs between two clips where the same foot or feet are planted with footsteps or planted keys, this option forces the foot/feet to stay planted during the transition. Default=On.

• **Continuity Range**—Sets an additional transition time after the actual transition, giving the foot time to get from its planted position to its keyframed location in the next clip. Range=0 to 100; Default=6.

• **Filter Hyper–Extended Legs**—Prevents a leg from straightening during a transition. This can occur when the COM moves in such a way that the foot can’t reach its planted position unless the leg goes completely straight. This option corrects the problem by raising the biped’s heel off the ground so the knee can bend. Default=On.

• **Max Knee Angle**—Sets the maximum angle that can be reached between the thigh and calf before the heel comes off the ground. An angle of 180 indicates a perfectly straight leg. A value of 160 or 170 indicates a slightly bent leg.

---

### Mixer Rollout

Select a biped. > Motion panel > Biped rollout > Mixer Mode

On this rollout, you can load and save MIX files (Motion Mixer files) (page 3–973). A saved MIX file can be loaded onto any biped in the scene, and motions in the mix will be automatically adapted to the biped’s size.

The Mixer rollout appears when Mixer Mode is turned on from the Biped rollout.
Load File—Loads a Motion Mixer file (.mix). These files include the following, which display in the Motion Mixer window when a MIX file is loaded:

- **Trackgroups**—Groups of tracks (page 3–1023) for selected parts of the biped.
- **Tracks**—Layer tracks (page 3–961) and transition tracks (page 3–1027) where clips and transitions reside.
- **Clips**—References to BIP animation files used in the mix.
- **Transitions**—Connections between clips on transition tracks.

Note: Loading a MIX file does not automatically open the Motion Mixer. Click Mixer on the Biped Apps rollout to open the Motion Mixer and see the loaded mix.

Save File—Saves the currently selected biped’s mix in the Motion Mixer to a MIX file.

---

**Animation Utilities**

3ds Max provides a number of utilities, available from the Utilities panel (page 3–778), to assist in animating scenes:

- **Follow/Bank Utility** (page 2–653) is an alternative to the Path constraint (page 2–398).
- **MACUtilities Utility** (page 2–665) lets you convert an imported TRC motion (page 3–577) into CSM format so you can map it onto a biped.
- **Camera Tracker Utility** (page 2–667) synchronizes a background by matching the movement of a 3ds Max camera to a real camera.
- **Dynamics Utility** (page 2–686) generates animation by simulating real-world physics.
- **Skin Utilities** (page 2–700) provide a method for copying skin data (envelopes and vertex weights) from one model to another.

---

**Follow/Bank Utility**

The Follow/Bank utility applies rotation keys to an object that already has a motion trajectory. The settings are similar to those found in the Path constraint. Use this when you have an object for which you’ve already assigned motion and want it to follow or bank along its trajectory, but don’t want to use a Path constraint.

The utility aligns the object’s X axis to the direction of motion. To change the orientation, change the
pivot orientation in the Hierarchy > Pivot panel before using this utility.

Although many of the settings are the same as in the Path constraint, this utility is not dynamic; you have to click the Apply Follow button each time you change an object’s animation or the utility settings. When adjusting banking settings, move to the point at which the object is at the sharpest turn, then alternately click Apply Follow and adjust the banking settings to get the right affect at the extreme corner.

Tip: You can also use an Orientation Constraint to manually control the rotation of the object as it moves through space. While this is not automatic, it allows more fine control on individual frames than other methods.

**Procedure**

1. On the Utilities panel, click the More button, and choose Follow/Bank from the list.
2. Adjust the options in the Follow/Bank Parameters rollout.
3. Select the objects you want to follow/bank.
4. Click the Apply Follow button.

   The objects orient themselves at the start frame, and follow or bank along their trajectories.

**Interface**

- **Selected Object group**
  - Displays the name of the current selection. If more than one object is selected, "Multiple Selected" displays.

- **Apply Follow button**
  - **Apply Follow**—Applies the settings and generates rotation keys. Each time you click this button, rotation keys in the specified range of frames (set in the Samples group) are deleted and regenerated.

- **Follow Options group**
  - Contains the parameters that specify whether or not to use banking, and the banking settings.
  - **Bank**—Turn on to cause the objects to bank as well as follow the trajectory.
Bank Amount—Adjusts the amount of the banking to one side or the other, depending on whether the value is positive or negative.

Smoothness—Controls how rapidly the roll angle changes as an object moves through bends in the trajectory. Smaller values make an object more responsive to subtle changes in the curve while larger values minimize jerkiness.

Allow Upside Down—Avoids the situation where an object flips when going around a vertically oriented path.

Samples group
Specifies the range of frames over which rotation keys are generated, and the number of keys to be generated.

Start—Specifies the first frame rotation keys are generated.

End—Specifies the last frame rotation keys are generated.

Samples—Specifies the number of rotation keys to be generated in the specified range.

Close button
Close—Exits the Follow/Bank utility.

1. In Track View, assign motion capture animation controllers to the specific tracks you want controlled by external devices.

2. After assigning the Motion Capture controller, open the Properties dialog for the track and bind the type of peripheral device(s). As an example, the Rotation Motion Capture controller has three rotational axes to which you can bind one device each.

3. After binding devices, adjust their settings and parameters in the lower portion of the Track Properties dialog. These controls vary depending on the type of device.

4. On the Utilities panel, open the Motion Capture utility. You can test and record your motion for any combination of tracks over any range of frames.

The following motion-capture devices are included with 3ds Max:

Mouse Input Device rollout (page 2–661)
Keyboard Input Device rollout (page 2–661)
Joystick Input Device rollout (page 2–662)
MIDI Device rollout (page 2–663)

Procedures
To assign a Motion Capture controller to tracks:

The first step in using motion capture is to assign motion-capture controllers to the tracks you want.

1. In the Track View hierarchy, highlight the Transform track you want.

2. Choose Controller > Assign.

The Assign Controller dialog is displayed.

3. Choose Motion Capture (might start with “Position,” “Float,” “Scale,” or other), and then click OK.
A Motion Capture dialog is displayed. Its title bar includes the name of the object and the track to which the controller is assigned. If a Data dialog opens instead, close it, right-click the track name, and choose Properties.

When you assign a Motion Capture controller, the previously assigned controller is maintained as a child of the Motion Capture controller. This lets you continue to adjust the object using standard transform controls, while still making motion-capture control available.

**To bind and adjust devices:**

1. After assigning a Motion Capture controller, determine the type of device that will drive the motion.

   Depending on the type of controller, you might be able to bind one or more devices. For example, a Rotation Motion Capture controller can have three devices, one for each axis of rotation. On the other hand, a controller for the radius of a cylinder would have only one device to control the radius value.

2. Bind the devices in the Properties dialog for the track.

**To specify a device:**

1. Click the Properties button while the Rotation track is selected.

   The Properties dialog for rotation motion capture includes three binding buttons (one for each axis.)

2. Click the Y Rotation button. In the resulting dialog, choose Mouse Input Device, and click OK.

   The lower half of the Properties dialog display controls specific to the new device. Assuming this is a segment that isn’t attached to another object, you want the horizontal mouse movement.

3. Under Mouse Input, choose Horizontal.

   The Scale spinner lets you adjust the relative effect of the mouse movement to the rotation. Flip reverses the rotational direction with respect to the mouse movement.

**Example: To set up the Joystick controller to move a Free camera:**

You set up the Joystick controller to move a Free Camera around on the XY plane. The Y movement of the joystick will affect the camera’s forward and backward movement, and the X movement of the joystick will rotate the camera. You’ll use Increment Based On Direction to allow the Y movement to be local to the camera rather than to the world.

1. Create a Free camera in the Front viewport.

2. In Track View, assign a Rotation Motion Capture controller to the Rotation track of the camera.
3. Right-click in the Rotation track to display the Motion Capture properties dialog.
4. Click the button beside Z Rotation, and assign a Joystick Input Device.
5. Under Joystick Axis, choose the X option (if it’s not already chosen).
6. Check Accumulate so that the rotation won’t return to zero each time you release the joystick.

**Example:** To set up the Position controllers of a camera for moving with a joystick:
The rotation of the camera about its world Z axis will be controlled by the X motion of the joystick. You’ll set up the Position controllers of the camera to move the camera forward and back with the Y motion of the joystick.

1. Assign a Position Motion Capture controller to the camera’s Position track, and access its Properties dialog.
2. Assign a Joystick Input Device to both the X Position and Y Position buttons.
3. Click the Edit Binding X button, and then choose the Y option under Joystick Axis.
4. Check Accumulate.
5. Click the Edit Binding Y button, and also choose Y under Joystick Axis.
6. Check Accumulate.

   The Y motion of the joystick will now affect both the X and Y positions of the camera.

**Example continued:** To add the increment based on direction options:
If you tested the camera motion at this point, moving the joystick forward or backward along the Y would produce a diagonal motion because the Position tracks would receive equal amounts of X and Y values. Adding the Increment Based On Direction options will change this.
1. Click the X Edit Binding button.
2. Under Increment Based On Direction, click the button beside Controller.
   A dialog appears with a list of controllers.
3. Find and select the Rotation Motion Capture controller for the camera.
4. Set the Direction option to Z (the local axis along which the direction points).
5. Set the Component option to X (matching the Edit Binding button).
6. Click the Y Edit Binding button.
7. Click the button beside Controller, and assign the Rotation Motion Capture controller.
8. Set the Direction option to Z, then set the Component option to Y.
9. Open the Motion Capture utility, turn on both tracks in the list, click the Test button, and move the camera while observing it in the Top viewport.

   As you move the joystick in the Y direction, the camera moves forward or backward. Moving the joystick in the X direction rotates the camera, but then, as you continue moving the joystick in the Y direction, the camera moves forward and back along its local axis.
Tests and records your animation. The first three buttons let you control the recording directly, while the Start/Stop button lets you use a MIDI device to control the recording.

**Start**—Starts a recording using the values set under Record Range below the Track list.

**Stop**—Stops the recording before the Out frame is reached. You can also stop a recording by pressing Esc or by pressing the right mouse button.

**Test**—Tests your motion. No recording takes place. Exit by clicking Test again, pressing Esc or clicking the right mouse button.

**Play During Test**—When turned on, and you click Test, the animation in the scene plays in a loop while you test your motion. Note that tracks in the Motion Capture list that are selected (marked red) won't play back because they're waiting for input from the assigned peripheral device.

**Start/Stop**—Displays the Start/Stop Trigger Setup dialog (page 2–659). You can choose the type of MIDI device that will control the recording.

**Enable**—Uses the assigned MIDI device for recording instead of the Start, Stop, and Test buttons.

**Tip:** In the Time Configuration dialog, you can reduce the viewport playback speed, test or record at the lower speed, and then reset the speed to normal to view the results.
Start/Stop Trigger Setup dialog

**Presets**—Choose the type of MIDI device. If you choose Media Control Station 2, you can use its buttons to Stop, Play, and Record. (The Media Control Station is a MIDI device containing standard VCR-style playback buttons along with a jog wheel.) By choosing Custom, you enable the remaining spinners in the dialog, where you can set specific channels and note numbers. You can also use Custom to customize the controls used by the Media Control Station.

**Channel**—Specifies the channel to which your MIDI device is assigned.

**Note Number**—The Stop, Play, and Record spinners that follow this label let you specify which note event triggers which function.

- **Stop**—This note event stops the playback or the recording. On the Media Control Station, this would be the square button. This is the equivalent of clicking the Stop button under the Record Controls group.
- **Play**—Plays the animation. This is the arrow button on the Media Control Station.
- **Record**—When this note is sent by itself, it’s the equivalent of clicking the Test button under Record Controls. To record the motion capture, you must press both Play and Record at the same time (the equivalent of clicking the Start button under Record Controls). You can press the Play button before or after the Record button and release the Play button before or after the Record button. The recording starts when the button is released.

**Tracks group**

The Tracks area displays all tracks that have been assigned Motion Capture controllers. You select the tracks that will be affected by the three buttons in the Record Controls group. Click a track to toggle its selection box on or off. Only the selected tracks displaying the red box are affected by the Record Controls group.

You can select the tracks either by clicking them, or by using the All, Invert, None buttons. In addition, you can create named selection sets of tracks. To create a named selection, click the tracks you want, and then enter a name in the Edit field above the track list. To select a previously named set, open the Edit window, and select it from the list. To delete a named set, select it from the list, and then click the Delete button at the right.

Note: A specific track can be in only one named selection at a time.
All—Assigns all tracks to the Record Controls group.

Invert—When tracks are selected, assigns the unselected tracks to the Record Controls Area.

None—Assigns none of the tracks to the Record Controls group.

By default, each track is provided a name consisting of the name of the object followed by a backslash and the name of the parameter. For example, Sphere01\Angle is an Angle parameter applied to one of the modifiers assigned to a sphere. You can rename the tracks in the Properties dialog, which you can access in Track View, or by double-clicking the track name in the Motion Capture utility. The upper rollout of each Properties dialog includes a Track Name field. Any name entered in the Track Name field appears in the Track list in the command panel, in the title bar of the Properties dialog, and beside the Data track in the Hierarchy list in Track View.

Record Range group

Specifies the frame range affected by the recording. You can also set a preroll range of frames (see below).

Preroll—Specifies the frame number where the animation begins playing when you press the Start button. If this number is the same or greater than the In number, the Preroll number is ignored. For example, if In: 0 and Out: 200, then a Preroll of -100 would give you 100 frames before the recording started, while a Preroll of 50 would be meaningless. If the range defined by Preroll and Out is larger than the current segment, the segment is temporarily enlarged during the recording.

In—Specifies the frame number where the recording begins after you click Start.

Out—Specifies the frame number where the recording ends after you click Start. You can stop the recording before this by clicking Stop.

Live During Preroll—When this is active, the motion capture is live through the preroll frames. The motion occurs, but isn’t recorded. This can cause sudden motion shifts at the In frame because your live motion might not match the animation when you reach the In frame. When this option is inactive, the motion is disabled or frozen until you reach the In frame.

Samples group

When the motion data is captured, it’s sampled at a rate relative to the current frame rate, which defaults to 30 frames per second. Increasing the frame rate increases the sample rate. The two radio buttons in this section allow you to choose one or two samples per frame. This is a shortcut that lets you sample at a field rate. If you’re rendering to fields, you don’t need to capture at 60 frames per second. Controllers will interpolate between the samples.

Reduce Keys—Reduces the keys generated by the motion capture.

Threshold—The value you enter in the Threshold field constrains how 3ds Max changes the selected track. The difference between the new animation and the original animation, at any frame, will be less than the threshold value.
Low threshold values closely match the original animation but may not greatly reduce the number of keys.

High threshold values produce the fewest keys but may not match the original animation with much accuracy.

Note: When Reduce Keys is active, there is additional calculation time after each completed recording.

Mouse Input Device rollout

Controls animation using the horizontal or vertical motion of the mouse. The available settings include the following:

**Horizontal/Vertical**—Specifies which mouse motion drives the animation.

**Scale**—Scales the relative effect of the mouse movement to the animation response (Spinner Value: float, 0 to 999,999)

**Flip**—Flips the direction of the response relative to the mouse movement. For example, if moving the mouse horizontally to the right produces a clockwise effect on a Rotation controller. Activating Flip will reverse the rotation to counterclockwise.

Keyboard Input Device rollout

Lets you assign most keyboard keys to drive the animation.

Key Assignment group

Click the Assign button, and then press any key. The assigned key appears in the list at right. Alternatively, you can open the list and select a key from it.

Assign—Click the Assign button, and then press any key. The assigned key appears in the lower list at right.

Drop-Down List—You can open the list and select a key from it.

Envelope Graph group

Displays a representation of the amplitude curve over time.
Envelope Parameters group

Specifies the time over which the envelope of the action takes effect, relative to the key pressing and release.

**Attack** — Displays the time it takes after pressing the key for the value to reach its maximum level.

**Decay** — Displays the time it takes after having reached maximum for the value to fall to that specified by the Sustain spinner.

**Sustain** — After the Attack and Decay, the value specified here is sustained until you release the key.

**Release** — After releasing the key, this is the time it takes for the value to fade out to zero.

**Parameter Scaling Area** — Sets the scale of the envelope and the range of the output value.

**Time** — Specifies the scale of the Attack, Decay, and Release parameters. The value represents the number of seconds contained in 1 unit. For example, if this value is 1.0, then an Attack value of 1.0 equals 1 second.

**Range** — Sets the maximum output value of the controller.

*Note:* This controller ignores the state of the \[Ctrl\], \[Alt\], and \[Shift\] keys.

*Tip:* Because a single keyboard key can only generate either a positive or negative value, if you want to control both directions of a Bend Angle, for example, use a List controller. First, make sure there’s a standard controller (such as a Bezier controller) assigned first in the list to maintain the center position. Then add two Keyboard Motion Capture controllers to the list (one assigned to one key, and the other assigned to a different key.) Set the range of one to the positive extent and the range of the other to the negative extent.

Joystick Input Device rollout

The Joystick Input Device driver was designed for the Microsoft Sidewinder joystick, which contains more controls than the standard joystick. You can use this device driver for standard joysticks as well.

Joystick Axis group

**X, Y, Z** — Specifies which joystick direction drives the animation. (Standard joysticks provide X and Y axes only. The Sidewinder provides the Z axis when you twist the joystick.)

**Throttle** — On the Sidewinder, this is a slider next to the stick.

**Scale** — Scales the relative effect of the joystick action to the animation response (Spinner Value: float, 0 to 999,999)

**Flip** — Flips the direction of the response.

**Accumulate** — When turned off, the joystick position represents an absolute position, and
you're limited to the "rectangle" defined by the limits of the joystick. When the joystick returns to its rest position, the value generated returns to zero. When this is turned on, the joystick represents a change in the current position. Moving the joystick forward, for example, can cause an object to start moving, and it will continue to move until you return the joystick to its rest position.

**Joystick Buttons group**

*Point-of-View Hat (Left-Right, Up-Down)—* The Sidewinder includes a mini-joystick on the tip of the main joystick. Specify the direction this joystick controls in the animation.

1, 2, 3, 4—Specifies one of four buttons in the Sidewinder joystick. They work similarly to the Point-of-View Hat, except that each button increases a direction value only while pressed. When you release the button, the value returns to zero (centered).

**Inc./Dec.**—One of three options available only when you choose one of the numbered joystick button options. This option (Increment/Decrement) means that the value is incremented when the button is down, and decremented when the button is up.

**Inc.**—When turned on, the value increments when the button is down, and stays at that value when you release the button.

**Absolute**—When turned on, the assigned parameters jumps to the value set in the Speed spinner when the button is down, and then jumps back to zero when you release the button. Use this for on/off animations, such as blinking lights.

**Speed**—Controls the rate at which the value changes when using either the Point-of-View Hat or the four buttons. When using a button option and the Absolute option, this specifies the value output when you press the button (Spinner Value: float, -999,999 to 999,999).

**Increment Based On Direction group**

Provides controls that let you derive the direction of movement from a Rotation controller. These options are used primarily when you're animating a first-person flythrough (such as when controlling a camera).

*Note:* The items in this area are only available when you select Accumulate in Joystick Axis.

**Controller**—Assigns a Rotation controller from which the direction will be derived.

**Clear**—Removes the assigned controller.

**Direction X/Y/Z**— Specifies the local axis that will be used as the direction. For a Free Camera, for example, this would be Z because the camera points in the Z direction. However, if you had a car that pointed along its Y axis, you’d use Y.

**Component X/Y/Z**— Specifies the edit binding to use. Match this to the Edit Binding button under Device Bindings. For example, if the Y Edit Binding button is selected, choose the Y Component option.

**MIDI Device rollout**

Controls animation using a MIDI device.
Chapter 12: Animation

MIDI Channel group
Contains 16 buttons. Click to specify the channel to which your MIDI device is assigned.

MIDI Trigger group
Defines the type of MIDI event (message) that will drive the motion. There are four options.
Note: When you choose this option, the note number or pitch defines the output value. The value is derived from where the note falls within the Note Range, specified in the Note Range group. When the note is at the bottom of the range, the value takes on the Min value specified under Parameter Scaling. When the note is at the top of the range, the value takes on the Max value from the same area. Anything in between is interpolated between the Min and Max values. (Note that Min doesn’t have to be less than Max.) The generated value will slide around as different keys are pressed. The harder a key is pressed, the faster the value changes. The Speed setting defines how fast, overall, the value changes as keys are pressed.

Velocity—When you choose this option, the velocity of the note pressed determines the output value. The notes set under Note Range merely specify which notes are valid to press. The value takes on the Min value until a key within the Note Range is pressed. When the key is pressed, the value approaches the Max value based on how hard the key was pressed. (The value actually travels along a parabola toward the Max value.) The Sustain setting defines how long it takes the value to move through the parabola. When you choose Variable, the sustain length is also scaled by how hard the key was pressed.

Pitch Bend—The MIDI instrument’s pitch bend knob defines the value. The Note Range doesn’t apply in this case and is disabled.

MIDI Controller—Specifies a note event when you’re hooked up to a different type of MIDI controller than the typical keyboard. For example, if you’re using a MIDI slider box, you would select the MIDI Controller option, and then use the # spinner to specify the note event for the specify slider.

Note Range group
Low Note/High Note—Set these to specify the low and high ends of the note range when the Note option under MIDI Trigger is turned on.

Parameter Scaling group
Contains the Min and Max spinners, which specify the range of generated values. See Note and Velocity.
MIDI Channel Viewer
Clicking MIDI Channel Viewer at the bottom of the MIDI Device rollout displays a dialog that lets you test your MIDI device to see which MIDI channel is receiving events, and which notes are being triggered.

MIDI Channel group
Provides a column of 16 buttons and progress bars representing the 16 MIDI channels. Select the channel from which you want to view note activity. The channel progress bars light up when any channel has an event.

MIDI Note group
The 11 Octave buttons let you select which octave you want to view. When a note is played in that octave, a corresponding progress bar lights up in the Note column.

MIDI Controller #—When using a different type of MIDI controller, such as a slider box, you can specify a note event, and then watch the corresponding progress bar light up when you activate that event. You can find the correct note number by activating the event while watching the Note Number field at the bottom of the dialog.

Channel—This is one of four text fields that display all of the values being generated by the MIDI device as you activate an event. The Channel field displays the currently selected channel.

Event—Displays the type of MIDI event being sent. This can be:
- Note On: 9
- Note Off: 8
- Pitch Bend: 14
- MIDI Controller: 11

Velocity—Displays the velocity, which has a different meaning, depending on the event. For the most common event, a note being pressed, this value represents the velocity at which the key was struck. Other events, however, might generate a continuous value. For example, a pitch bend event transmits the position of the pitch bend.

Note Number—Displays the corresponding note number for the event. When you’re using a non-keyboard MIDI device, such as a slider box, you can use this to identify the note number of a specific slider, for example.

MACUtilities Utility
Utilities panel > More button > MACUtilities
You can use the Motion Analysis Corporation utility to convert motion data originally recorded in TRC format into CSM. This allows you to easily map the motion onto a biped.

A MNM (Marker Name) file is needed to determine how to convert the marker names from the incoming data into the CSM naming convention. You can either load an existing MNM file or create a new one using the MNM Creator/Marker Selection dialog.

Procedures
To convert a TRC file into CSM:
1. Click the Browse... button next to Create.
2. Highlight a MNM file in the Select Mapping File... dialog. Click Open to confirm your selection. The MNM file serves as a naming convention reference for the TRC conversion.
3. Click the Browse... button over Convert TRC To CSM.
4. Highlight a folder in the Choose CSM Files Destination Folder... dialog. Click Use Path to confirm your selection.
After the conversion, the resulting CSM file is saved in this folder.

5. Turn on Use MNM Filter File.
6. Turn off Use TRC Filename.
7. Click Convert TRC to CSM.
   
   A Select Source TRC Files... dialog opens.
8. Highlight a TRC file and click Open to confirm your selection.
   
   A Selected Target CSM File... dialog opens.
9. Either highlight an existing CSM file to overwrite or enter a new filename. Click OK to confirm your selection.

Your file is converted into CSM format. You can now load it onto a biped.

**Interface**

**MNM Mapping File**—Displays the path and name of the chosen MNM file.

**Create**—Launches the MNM Creator/Marker Selection dialog, which creates a MNM file to use in the conversion process.

**Browse...**—Lets you pick a custom mapping file to use in the conversion process.

**CSM Output Folder**—Displays the folder path where the CSM file is generated.
Browse...—Lets you pick a folder in which 3ds Max saves the generated CSM file.

Convert TRC To CSM—Lets you first pick the TRC file to convert. The resulting CSM file is named after the original TRC file.

Note: If Use TRC Filename is turned off, a second dialog opens so you can pick an existing CSM file to overwrite or create a new one.

Options group

Use MNM Filter File—When on, the MNM file is used in the conversion process. Default=on.

Note: Turn off if the TRC marker names already follow the CSM standard naming convention.

Batch File Conversion—Enables you to pick multiple TRC files to convert.

Tip: Use this option to save time when you need to convert multiple TRC files.

Use TRC Filename—When off, you can customize the resulting CSM filename. When on, the CSM file is named after the TRC file. Available only when Batch File Conversion is off. Default=on.

Translation Offset group

Enable—Turn on to add an offset to the resulting data's position.

TRC Space/3ds max Space—Choose between an offset space relative to the TRC data's root or to your scene.

XYZ—Sets the offset value for each position axis.

---

**Camera Tracker Utility**

Utilities panel > Utilities rollout > More button > Utilities dialog > Camera Tracker

The Camera Tracker utility animates the movement of a camera inside 3ds Max to match the movement of a real camera that was used to shoot a background movie.

For detailed Reference information about each Camera Tracker Utility rollout see:

- Camera Tracker: Movie Rollout (page 2–670)
- Camera Tracker: Movie Window (page 2–671)
- Camera Tracker: Motion Trackers Rollout (page 2–673)
- Camera Tracker: Movie Stepper Rollout (page 2–676)
- Camera Tracker: Batch Track Rollout (page 2–678)
- Camera Tracker: Error Thresholds Rollout (page 2–677)
- Camera Tracker: Position Data Rollout (page 2–679)
- Camera Tracker: Match Move Rollout (page 2–680)
- Camera Tracker: Move Smoothing Rollout (page 2–682)
- Camera Tracker: Object Pinning Rollout (page 2–683)

For additional information on using the Camera Tracker Utility see:

- Requirements for Camera Tracking (page 2–669)
- Camera Tracker: Troubleshooting (page 2–685)

**Procedure**

To generate a camera match-move:

1. Open the working scene in 3ds Max.
The scene should have a Free camera to be match-moved, as the tracker does not create one. The scene also should have a set of Point or CamPoint helper objects positioned in 3D to correspond to the tracking features. Optionally install the movie as an environment map-based background image in the match camera viewport. This is needed if you want to render a composite using the match-move or checking match accuracy. This doesn’t automatically display the background image in the viewport. Use Views > Background Image to select the background movie and display it in the viewport.

2. Open the movie file in the Camera Tracker utility and create a set of feature tracking gizmos for each of the tracking features in the scene.

3. Position the Feature Selection box and Motion Search box for each gizmo so that they’re centered on the features and have motion search bounds large enough to accommodate the biggest frame-to-frame move of the features throughout the frames that will be tracked.

4. Associate each tracker with its corresponding scene point object.

5. (Optional) Use the Movie Stepper rollout to set the start and stop frames for each tracker if it’s out-of-view for any of the frames that will be matched. These specify the frame range during which the tracker is visible in the scene and will be tracked as part of the matching process. This mechanism allows you to match a
move in which the view passes through a field of features with only some of them (at least six) visible at any time.

6. (Optional) Set up manual keyframes for each tracker at frames in which the feature radically changes motion or shape or is briefly occluded and so might be difficult for the computer to track. If you want, you can do this after a tracking attempt indicates where tracking errors occurred.

7. Perform the feature track using the Batch Track rollout. This is often an iterative process: correcting for tracking errors by tuning start and stop frames or manually repositioning the gizmo and motion search boxes at error frames. When you reposition a gizmo at some frame, you establish a new target feature image and subsequent frames up to the next keyframe will be retracked. You can use the error detecting features in the tracker to step through possible tracking errors. When complete, this process builds a table of 2D motion positions for each feature. You can save this to disk using the Save button on the Movie rollout.

8. Choose the camera that will be matched in the Match-Move rollout, select which camera parameters you want to estimate, set the movie and scene animation frame ranges and perform the match. This generates a keyframed animation of the selected camera parameters.

9. Check the match for obvious errors and review the tracker gizmo positions at these frames. You can manually adjust gizmos at these frames and the matcher interactively recomputes the camera position.

10. (Optional) Apply smoothing to selected camera parameters and recompute a compensating match for the other parameters.

The Camera Tracker also has the ability to animate 3ds Max geometry to follow or match the video by following the movement of a tracker in a 2D plane. For this type of animation scene measurements aren’t required. Use the Object Pinning rollout of the Camera Tracker to create this type of tracking.

Requirements for Camera Tracking

To use the camera tracker, you need the following:

- Movie footage in one of the file formats that 3ds Max supports, such as AVI or MOV. If you have sequential still images, you can use an IFL (Image File List). The file selector can automatically generate an IFL file by selecting the file name and turning on the sequence button. Or use the IFL Manager Utility (page 3–619) to create an IFL file.
• A set of trackable features in the movie, such as wall markers, balls, corner points and so on, for which position measurements are known. The tracker will track most small features with good contrast to their surroundings, have a well-defined position in space, and are unique within their frame-to-frame areas of movement. There must be six or more tracking features in the scene at any one time, at least two of which must be non-coplanar with the others, for example four on the ground and two elevated or three on one wall and three on another. For maximum match accuracy, you should use as many features as you can and select the features that are distributed as widely as possible over the scene. The features don’t have to be in any particular planes.

• A 3ds Max scene file in which a set of point objects have been created and positioned in 3D corresponding to all the tracking features in the scene. The objects should be point or CamPoint helper objects. The tracker will match-move a selected Free camera in the scene, so you need to have at least one Free camera. You can place and orient it anywhere in the scene.

**Interface**

- **Movie file**: Selects and opens the movie that will be tracked. You can open any image file format that 3ds Max supports. If you use sequential still-image files, you will use an .ifl (image file list) file. You can create the .ifl file using the IFL Manager or using any bitmap selector dialog by choosing Sequence. When you open the movie file, it’s displayed in a Movie window.

- **Display Movie**: Reopens a closed or minimized Movie window. You use the Movie window to setup and adjust feature tracking gizmos and to browse through the movie. For more details on working with the Movie window, see Motion Tracker rollout (page 2–673).

- **Show frame**: Allows you to step through the movie displayed in the Movie window. Alternatively, use the Movie Stepper rollout, which provides additional browsing controls.

- **Deinterlace**: Causes the tracker to apply a video deinterlacing filter to the movie frames. If the movie comes from a video source and the features you’re tracking show marked interlacing, you should deinterlace the video to improve tracking.

**Camera Tracker: Movie Rollout**

Opens the movie for tracking. Also provides controls for the display of the movie, including fade display to improve the visibility of the trackers. Provides controls for loading and saving MOT files in which tracker information is stored.
accuracy. If the movie was digitized from film, you should not perform deinterlacing because the results will be less accurate. The deinterlacing is performed temporarily on loaded frames and doesn’t affect the original movie file.

**Off**—Disables deinterlacing. When no filtering is required click this.

**Odd**—Interpolates using the odd lines.

**Even**—Interpolates using the even lines.

**Fade Display**—Fades the movie in a Movie window by 50 percent. Use this to see the tracker gizmos more clearly.

**Auto Load/Save**—Saves the state of a tracking setup and any position data you’ve produced to a special file associated with each movie. Selecting Auto Load/Save Settings causes the tracker to keep this settings file up-to-date automatically as you work in the tracker. You can force a save at any time by clicking the Save button. Whenever you open a movie file in the Camera Tracker with Auto Load/Save on, the tracker reloads the state of the tracking session from this settings file.

With Auto Load/Save Settings on, the tracker constructs the setting file automatically and places it in the same folder as the movie, named with the same prefix as the movie but with file type MOT. If you move the movie file to a new folder, move the MOT file with it so the tracker can find it. You can delete this file if you want to clear the settings or if the file becomes corrupted for any reason.

When AutoLoad/Save is turned off, you can open a different movie file either with an empty tracker state or into the existing tracker state or save the current tracker state into a new file. The name of the current tracker file is displayed at the bottom of the Movie rollout.

**Save**—Saves the state of the tracking setup, and any position data produced to the current MOT file.

**Save As**—Saves the current setup into a new MOT file. This file becomes the destination for subsequent Save operations.

**Load**—Load the tracker setup and position data from another file.

---

**Camera Tracker: Movie Window**

The tracker gizmo displayed in the Movie window consists of two enclosed boxes, a central pair of cross hairs, and a tracker number. The inner box surrounds the feature that will be tracked and is called the *feature bounds box*. The outer box defines the frame-to-frame search and is called the *motion search bounds box*. You should place the central cross-hair over the feature as close as possible to the point corresponding to the placement of its scene point object. It’s this center coordinate that’s used in the camera match-move correlation between image feature and scene Point coordinates.

You should make the feature bounds box large enough to enclose the feature and some of the surrounding images enough to give the feature a contrasting background of several pixels.
Chapter 12: Animation

The motion search bounds defines the area in which the feature will be searched for from frame-to-frame. This bounds box moves with the feature box, so the area is relative to the current feature at each frame. It’s important to estimate this search area well. If it’s too large, the matching process will be unnecessarily slow and there’s more chance of other features in the search area making the search ambiguous; if it’s too small, tracking errors will occur. It might be useful to review the movie that will be tracked on a real-time playback device like a video deck and estimate feature moves beforehand. If you set the Max Move/Frame spinner to the maximum move before creating the tracker, its motion search bounds box will be set to accommodate this move for you. You can also adjust this box at any time in the Movie window.

Note: It’s possible to change the search bounds box for different frame ranges in the movie, so you can optimize your search capabilities. See Keyframes and Position Data (page 2–679).

Working with the Movie Window

Displays the current frame of the movie being tracked and any active tracker gizmos for that frame. You can open and close the window using the Display Movie check box in the Movie rollout or minimize it using the standard window title bar controls.

When you first open a movie, 3ds Max sizes the window so it will fit on the screen and this might result in an automatic zoom out if the image is too big.

You can resize the window by dragging its sides or corners. You can zoom around in and out of the window using the tracker gizmo controls.

Working with the Tracker Gizmos

There are several ways to work with gizmos in the Movie window.

• Selecting: You need to select a gizmo to work on it. You do this by clicking anywhere inside its bounds in the Movie window or by clicking its entry in the tracker list box in the Motion trackers rollout. The selected gizmo displays positioning handles at the corners of both its bounds boxes. You can also select a gizmo by typing its number on the keyboard. A selected gizmo has click-selection priority in the Movie window. If several gizmos overlap, they make it hard to select and adjust the gizmo you want. You can select it first in the Motion Trackers rollout list; it remains selected for adjustment when you click it in the Movie window.

• Zooming: You can zoom in and out on the selected gizmo by pressing the \[I\] and \[O\] keys, for “in” and “out,” respectively. Each time you press \[I\] or \[O\], the window zooms in or out by a factor of 2 and centers the selected gizmo in the window. Pressing \[R\] resets the zoom factor to 100 percent whether you have a gizmo selected or not. The Movie window has to be active to work. You can make it active by clicking it.

• Tabbing: You can move among successively numbered gizmos by pressing the \[Tab\] key. If the gizmo you’re searching for is out of view, because you’re zoomed in, the image will be repositioned in the window to bring the newly selected gizmo into view. Tabbing while you’re zoomed in provides a quick way to step through the gizmos to check their fine positioning.

• Positioning: You can reposition a gizmo by dragging anywhere within its bounding boxes, providing you don’t click one of the eight box-corner handles. You can nudge a gizmo in single increments by pressing one of the arrow keys on the keyboard. The minimum increment that a gizmo will move depends on the zoom factor and the subpixel-tracking level. The increment is the smaller of either a single screen pixel in the current window or the subpixel
increment selected. So, if you’re zoomed out two times and the subpixel increment is 1/16 of a pixel, the nudge increment is four image pixels, due to the zoom. However, if you’re zoomed in five times, the nudge increment is 1/16 of an image pixel, due to the subpixel level.

- **Bounds**: You adjust the bounding boxes by pressing and dragging the handles of the box you want to adjust. Dragging the handles of the inner feature bounds box adjusts the opposite corner symmetrically to keep the gizmo center fixed.

Typically when setting up tracker gizmos you should create and position them all roughly in a zoomed-out view, then zoom in on one of them, fine-tune its position and bounds, then tab to the next gizmo and repeat.

**Movie Window Keyboard Shortcuts**

You can use the following keyboard shortcuts in the Movie window:

- **I,i**: Zooms in on a selected gizmo.
- **O,o**: Zooms out on a selected gizmo.
- **R,r**: Resets zoom level to 100 percent.
- **Tab**: Selects next numbered gizmo, cycles back to first gizmo after the last.
- **[digit]**: Selects the numbered gizmo, only works for gizmos 1 to 10 (0=10).
- **Arrow Keys**: Nudges the gizmo in the direction of the arrow.

**Camera Tracker: Motion Trackers Rollout**

The Camera Tracker utility’s Motion Trackers rollout sets up and controls the image feature trackers. All the trackers created are listed here: showing enable check mark, tracker number, associated scene point object name, and active frame range. To select a tracker, click in the list. Provides controls for subpixel tracking as well.

**Interface**

![Motion Trackers Interface](image)

- **On**—When turned on, the feature will be tracked in the image when the movie is stepped through in the Movie Stepper, or when a full track is performed. An X appears in the tracker list when turned on.
- **Off**—When turned off, the tracker will sit at the closest known position prior to the current frame. Because feature tracking is computationally intensive, sometimes it’s useful to disable the trackers you’re not working on to speed up movie stepping.
- **All**—Enables all the trackers.
- **None**—Disables all the trackers.
- **New Tracker**—Creates a new movie feature tracker. This places a feature tracker gizmo in the center of the Movie window and a new entry in the tracker list. The new tracker takes on the parameters currently displayed under Tracker Setup. You can change these parameters after you create the tracker, but it’s often useful to set the Max Move Per Frame parameter prior to creating the new
tracker as this automatically establishes an initial search bound for the tracker gizmo.

**Delete Tracker**—Deletes the selected tracker from the list and the Movie window.

**Tracker Setup group**

Sets up the parameters for the currently selected tracker. Any tracker you create will take its initial parameters from the current values in this group.

**Scene object**—Associates a tracker with a scene point object that corresponds to the image feature in the Movie window. Pressing this button puts 3ds Max into standard object picking mode. When you've selected the object, the entry in the tracker list and the text in the button change to the name of the selected object. You can change the connected object at any time by pressing this button.

It's recommended that you use point or CamPoint helper objects, although you can use any 3ds Max object. The tracker uses the pivot point of the selected object as the correlation reference point during the match computation.

When you set up a tracking project, you can make the tracker save the setup in a .mot settings file. The association between tracker and scene point object that you set up here is saved as a scene object name. If you reload the movie in the tracker, the object association is reestablished using the object’s name. This means you must be careful to name the point objects uniquely, otherwise you might establish incorrect associations. Further, you must load the working scene in 3ds Max before opening the movie in the camera tracker utility, so the named objects can be found. If you happen to open the movie first, the object names in the Tracker list will all read "<none>". Simply reopen the movie in the tracker and it will establish the connections correctly.

**Match weight**—Sets the camera matching priority separately for each tracker. Use this to improve the match accuracy for features close to where a computer graphics generated element will be inserted. It helps to minimize sliding and jitter in that part of the scene.

The match-move algorithm works by adjusting the camera to minimize the error between the feature objects seen through the camera and their associated feature points in the movie plate. With all weights set to 1, the algorithm randomly distributes the error between all the object projections and their tracking features. If you bump the Match Weight of a tracker, it redistributes the error in favor of that tracker, reducing the distance between that tracker’s feature and object projection, while possibly increasing the error in other trackers. If you bump weights on two or more features, the locking may progressively lessen, since the algorithm distributes the improvements between the high-weight trackers. Use weights of two to six to get a good lock.

**Max Move/Frame**—Sets the maximum number of pixels that the tracked feature moves from frame-to-frame over the entire tracking range and establishes an initial motion search bounds box for newly created trackers. You can also set this dynamically by adjusting the motion search bounds box directly in the Movie window.
**Resample on error**—You can make the tracker identify possible tracking errors and you can use this during a manual tracking review and during actual tracking to correct errors. Typical sources of error include frame-to-frame jumps greater than the search bounds, image contrast changes, or a feature changing shape over a sequence of frames, such as a corner might if the camera moves by it. The error detector is controlled by measurement thresholds set in the Error Thresholds rollout.

When you place a gizmo on some frame, a keyframe is created and a new target feature image is sampled at that frame for searching in subsequent frames. Turning on Resample On Error causes the tracker to detect errors during tracking. If one is found, it backs up to the last good frame and places a new keyframe there causing a new target feature image to be sampled at that frame and continues tracking from that frame.

**Subpixel Tracking**—Usually, an image feature won’t move an integral number of pixels from frame-to-frame. With pixel-level tracking, however, the nearest estimate for a feature center is always at a pixel boundary. This can lead to camera match errors. With subpixel tracking you can zoom in on a feature and position its gizmo within a pixel. This makes the tracker attempt to track at that resolution by up-sampling the target image and search bounds, thereby improving match accuracy.

You can turn on subpixel tracking selectively for each tracker by choosing a level in the Subpixel Tracking drop-down menu on the Motion Trackers rollout. This defines the resolution at which feature tracking is performed in the tracker up to 1/32 of a pixel.

Two things happen when you select a subpixel level:

- The grid over which you can position a tracker gizmo in the image window is adjusted to the new subpixel level. You can position the gizmo can be positioned inside pixels in zoomed views. You can zoom in on a tracker gizmo by selecting it and pressing the I or O key to zoom in or out, respectively.

  - Feature searching is performed on internally scaled-up versions of the target image feature and portions of the search window. These versions are scaled up in inverse proportion to the subpixel level using bicubic interpolation, which allows the feature tracker to search at this scaled pixel level.

When manually positioning gizmos at keyframes, it’s crucial that you zoom in enough so you can place the gizmo in the center of the feature to the degree of accuracy allowed by the selected subpixel level. If you don’t do this, the tracker won’t be able to track the correct center at the selected resolution.

Tip: Even though the feature is first tracked to the nearest pixel at whole pixel increments and then tracked at the subpixel level within that one pixel range, the tracking time can increase significantly in proportion to the inverse square of the subpixel level. For this reason it’s suggested that you set the subpixel level to as low as possible. Usually 1/8 of a pixel is adequate for features well distributed around the scene. Use greater levels if the features are fairly close together, or move very slowly within the frame.

You can also reduce feature tracking times by making the inner feature bounds box in the gizmo as tight as you can while still retaining a couple of pixels worth of surrounding contrast. Search times are proportional to the feature bounds box size.

**Track Range**

Use these when a feature moves off-screen or is not visible in the Movie window.

**Set Start**—Sets the start of the active frame range for a tracker.
Set Stop—Sets the end of the active frame range for a tracker.

You use the Set Start and Set Stop buttons in the Setup box together with the Movie Stepper rollout to set the active range. Pressing the buttons will set the start or stop point at the frame currently shown in the Movie Stepper.

Tracker Keyframes and Position Data

Any time you manually position a tracker gizmo, such as at the first frame or at some tracking error, you create a special keyframe position. The tracker never attempts to reposition these keyframes, but uses them as start points for the frames that follow them up to the next keyframe. At keyframes, you can adjust the position and the feature or search bounds.

During tracking, the selected feature at a keyframe is sampled and that feature becomes the search target for subsequent frames. Using any adjusted search bounds up until the next keyframe, provides the start point, target feature, and search bounds box for the frames that follow.

The position data for each frame in each gizmo can be one of three possibilities:

- A keyframe defining a new start position, target feature image, and search bounds box.
- A tracked position.
- Unknown.

All frame positions except the first are initially unknown and will be named as tracking proceeds or gizmos are positioned. When you manually set a keyframe, any previously tracked positions following that keyframe up until the next keyframe are deleted and so become unknown. The Complete Tracking button in the Batch Track rollout searches for unknown positions in the currently enabled trackers and tracks those frames. The Check Status button in the same rollout checks for any currently unknown positions as well as tracking errors. See Batch Track Rollout (page 2–678).

Camera Tracker: Movie Stepper Rollout

Utilities panel > Utilities rollout > More button > Utilities dialog > Camera Tracker > Movie Stepper rollout

The Camera Tracker utility’s Movie Stepper rollout browses through the movie during the tracking phase either to set start and stop frames, to review tracking results or to manually perform a track over a sequence of frames. The Movie Stepper rollout consists of a frame counter, a set of stepper buttons, and some option check boxes.

Interface

<table>
<thead>
<tr>
<th>Movie Stepper</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Movie frame: 0</td>
<td></td>
</tr>
<tr>
<td>&lt;&lt;</td>
<td></td>
</tr>
<tr>
<td>Off</td>
<td>Feature tracking</td>
</tr>
<tr>
<td>Clear tracking to end</td>
<td></td>
</tr>
<tr>
<td>Step keyframes</td>
<td>Show track</td>
</tr>
</tbody>
</table>

Movie Frame Counter—Advances the Movie window to the designated frame.

VCR controls—Navigates through the movie in the Movie window:

- <<—Steps to the start frame of the selected tracker.
- <10—Steps back 10 frames.
- <—Steps back one frame or keyframe if Step Keyframes is turned on.
>—Steps forward one frame or keyframe if Step Keyframes is turned on.

>10—Steps forward 10 frames, either directly or one frame at a time if the Master Track Enable check box is turned on.

>>>—Steps forward to the end frame of the selected tracker, either directly or one frame at a time if the Master Track Enable check box is turned on.

Feature Tracking—If turned on, any forward steps will cause frame-by-frame feature tracking to be performed for all enabled trackers with unknown position data at the frames you previously stepped through. You can use this to perform a tracking check while testing bounds settings or to review tracked positions one frame at a time. The tracker also moves the gizmos to previously tracked positions, so you can review tracking results a few frames at a time. If you want, you can force a retrack by nudging a keyframe gizmo back-and-forth which causes the gizmos to drop all subsequent tracked positions up to the next keyframe.

Note: Make sure this button is turned off if you just want to step through the movie without tracking, such as when browsing through the movie to find and place Start and Stop frames for trackers that come on screen or go off screen during the tracking range.

Clear Tracking to End—Removes all tracked positions and keyframes from the current stepper frame onward for the currently selected tracker. This is often helpful if you have too many errors and error correcting keyframes at the end of a track and you want to clear them and track to the end again.

Step Keyframes—Modifies the operations of the single-step buttons in the Movie Stepper. If turned on, the single step buttons step immediately to the next or previous keyframes, allowing you to browse through them quickly. In this mode, feature tracking is disabled.

Show Track—Displays a visible tracking line in the Movie window for the currently selected tracker. This button shows where the tracker has currently tracked. A red line is displayed for tracked segments, a white dashed line for segments still to be tracked. White dots are centered on each frame position with a green box around each frame position at which you or the tracker create keyframes.

Live Camera Match—Enabled after you set up the match parameters and select a match camera in the Match rollout. If turned on, the match camera position is recomputed and adjusted as you move gizmos in the Movie window. This can be useful for making corrections to bad match frames by adjusting the trackers or to check the effect of tracker placement on the match computations. This is best done with the nudge arrows. Turn on the 3ds Max Auto Key button to record adjusted match camera positions.

Sync Animation—Controls whether the scene time slider is advanced in step with the movie frames during stepping. This is sometimes useful if you have the movie set up as an animated background image in the match camera window. Check camera positioning at the same time you check feature positioning. This can slow stepping substantially, so it’s turned off by default.

Camera Tracker: Error Thresholds Rollout

The Camera Tracker utility’s Error Thresholds rollout attempts to identify feature tracking errors by taking measurements and comparing them to the thresholds that you set up in this rollout.
can use this detection can be used both during a manual tracking review (see Batch Track Rollout (page 2–678)) or during actual tracking to correct errors using the Resample On Error control in the Motion Trackers setup rollout (page 2–673).

**Interface**

<table>
<thead>
<tr>
<th>Error Thresholds</th>
</tr>
</thead>
<tbody>
<tr>
<td>Match error: 0.05</td>
</tr>
<tr>
<td>Variance delta: 0.4</td>
</tr>
<tr>
<td>Jump delta: 5.0</td>
</tr>
</tbody>
</table>

**Match Error**—A sum-of-differences-squared measure in RGB space of the best match in the current frame to the feature target from the previous keyframe. The error shown is a percentage of the maximum possible image difference. Good matches are usually below 0.05 percent.

**Variance Delta**—The difference in RGB color variance between the feature target image and the current best match. This measures whether the target and match have similar color ranges and can compensate for mistakes made by the sum-of-differences measure.

**Jump Delta**—The tracker computes a moving average for the preceding five frames and measures the difference between that average and the jump in the current frame. If this difference exceeds the current Jump delta threshold, a potential error is flagged. If the threshold is set to five, any jump in the current frame that’s five pixels more than the average jump in the last five frames is flagged. This picks up sudden accelerations rather than just large jumps.

You can adjust the thresholds as needed and enable or disable individual measures in the detector using the check boxes to the left of each measure.

**Camera Tracker: Batch Track Rollout**

The Camera Tracker utility’s Batch Track rollout performs feature hands-off tracking once the trackers have been set up. You can set up a set of trackers, start a batch tracking of them all, and then use the other tools in this panel to check for and review detected tracking errors. This panel also checks for tracking completion.

**Procedure**

**To review and correct tracking errors:**

1. Select an error in the list.
2. Browse through the errors in sequence by repeatedly clicking Next, under the list.
3. When you’ve selected an error, the associated tracker gizmo is selected and brought into view and the movie is set to the frame at which the potential error was detected.
4. If there is indeed an error, adjust the gizmo in the Movie window to correct it, and place a new keyframe.
5. If inspection shows that there isn’t an error, the thresholds may be set too finely, so try adjusting the associated threshold and running Check Status again. This is often a good way to calibrate the thresholds for your scene, but be careful not to increase them too much and miss a real error.
6. To clear an entry out of the list, click the Clear button. This is basically a cosmetic action that removes items from the list that you’ve either fixed or determined are not errors while working through the potential errors. If you perform a Check Status again, some of the errors may show up as well.
Interface

- Batch Track
  - Complete Tracking

Tracking Status
  - Check status
  - Incomplete: ?
  - Error: ?

Tracking error review

Complete Tracking—Searches for unknown positions in enabled trackers and undertakes tracking for those frames. It performs this optimally, and only tracks the frames for which enabled trackers have no position data.

Tracking Status group

Check Status—Scans for tracking errors and untracked frames. It displays two lines of information underneath it in the Status box:

Incomplete—Lists the tracker numbers with untracked frames in their active frame ranges.

Errors—Lists the tracker numbers containing one or more tracking errors as determined by the current error threshold settings.

Tracking Error Review group

Displays all the potential errors in a list. For each error the list shows a tracker number, error frame and details about the error. The details include a code identifying the thresholds and the error measure.

Error Codes

Me—Match error threshold exceeded.

Vd—Color variance delta threshold exceeded.

Jd—Jump delta threshold exceeded.

In each case, the number following the code is the actual error measure. You can see how the error measure compares to the current thresholds in the Error Thresholds rollout. If you adjust the thresholds in this rollout and then rerun the Check Status again, the list is refilled with those points in the tracking that exceed the newly adjusted thresholds.

Next—Moves to the next error in the list.

Clear—Clears an entry out of the list.

Camera Tracker: Position Data Rollout

Utilities panel > Utilities rollout > More button > Utilities dialog > Camera Tracker > Position Data rollout

Interface

- Position Data
  - Apply to
    - Selected tracker
    - Enabled trackers
    - All

Clear to end  Show data
Clear all  Export

Apply to group

Contains three radio buttons that control which trackers will be operated on by the action buttons below it.

Selected Tracker—Operates on the currently selected tracker.
**Enabled Trackers**—Operates on all the enabled trackers in the Motion Trackers rollout.

**All**—Operates on all the trackers.

**Clear to End**—Clears the position data in the trackers specified in the Apply To group from the current Movie Stepper frame onward. This is useful for clearing out and redoing a portion of the tracking.

**Clear All**—Clears all the position data in the trackers specified in the Apply To group.

**Show Data**—Opens a text window that displays the position data for the trackers specified in the Apply To box. The display includes some title lines showing the tracker number and associated tracking object followed by comma separated columns of numbers for the position data one row per frame. All rows contain at least three columns: frame number, X position, Y position. Keyframe frames also contain another eight columns: feature bounds left, top, right, and bottom, and Search bounds left, top, right, and bottom. The coordinates in decimal pixels show any subpixel tracking as decimal fractions.

The text window is a standard MAXScript source editor and you can copy, edit or save the contents to file.

**Export**—Creates a text file containing position data for the trackers specified in the Apply To group. Pressing this button displays a standard Save File dialog asking for the location and name of the file you’re creating. The file type defaults to .csv, the comma-separated value format readable by Excel and other data processing applications. The format of the data is exactly as for the Show Data command described previously.

---

**Camera Tracker: Match Move Rollout**

Utilities panel > Utilities rollout > More button > Utilities dialog > Camera Tracker > Match Move rollout

The Camera Tracker utility’s Match Move rollout automatically generates a camera animation by correlating the 2D position data of the movie features gathered during the tracking phase with the associated 3D feature points in the 3ds Max scene.

**Interface**

<table>
<thead>
<tr>
<th>Match Move</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Camera:</strong> none</td>
</tr>
</tbody>
</table>

**Match**

- **FOV**
- **Roll**
- **Pan**
- **Tilt**
- **Truck H.**
- **Truck V.**
- **Dolly**

**Match Range**

- **Movie start:** 0
- **Animation start:** 0
- **Frame count:** 101

**Generate Keyframes**

**Max. pixel error:**

**Show errors**

**Camera**—Enters an object-picking mode for you to select the camera that you will match-move. You can either select the camera directly in the scene or
press [H] to open the Select Objects dialog (page 1–78). Once selected, the camera name is placed in the picker button, and other buttons and controls are enabled in the utility. The selected camera is remembered in the MOT settings file and restored on reopening the movie in the camera tracker. As with the tracker point scene objects, the camera name is stored and used when reloading, so make sure it’s unique. The camera selected must be a Free camera. It can be at any position and orientation in the scene.

**Match group**

Lets you choose which camera parameters will be estimated during the match-move. Those parameters turned off will be derived from the current Camera animation or position, so it’s possible to pre-position or pre-animate the match camera with known moves or parameter settings and have the matcher estimate just the missing parameters. The accuracy of the estimation process increases substantially as the number of parameters that need estimation decreases.

- **FOV**—Camera FOV (field-of-view).
- **Pan**—Rotation about the local camera Z axis.
- **Tilt**—Rotation about the local camera X axis.
- **Roll**—Rotation about the local camera Y axis.
- **Dolly**—Movement along the local camera Y axis.
- **Truck-H**—Movement along the local camera X axis.
- **Truck-V**—Movement along the local camera Z axis.

**Match Range group**

Let’s you set the range of frames that will be matched to set up the relationship between the movie frames and the 3ds Max scene animation frames. By default, the start frames are both set to zero and the frame count is set to the smaller of the number of frames in the movie or the scene animation. Setting a different Movie Start or Animation Start frame lets you position the movie frame range relative to the animation frame range. The position data for a match will be taken from the tracker frames starting at the Movie Start spinner value and the camera will be matched and animated starting from those frames.

- **Movie Start**—Sets the start of the range to be matched in the movie.
- **Animation Start**—Sets the start of the range in the animation. Use this if the animation range is different from the movie range.
- **Frame Count**—Sets the number of frames to be matched.
- **Reset Ranges**—Reloads the maximum frame number and count ranges into the match range spinners from the current movie and 3ds Max scene settings. This is useful if you change the animation frame range in the scene while the tracker is open.
- **Animate Displays**—Controls whether the 3ds Max viewport appears and if the Movie window updates frame-by-frame to show the match results. This display update can be very time-consuming, so it’s often best to leave this turned off and review the match results by looking at the Camera function curves in Track View or by stepping through the 3ds Max animation a frame at a time after the match.
- **Generate Keyframes**—Generates keyframes for the estimated parameters on each frame.
- **Match-Move**—Starts the match process.
- **Max. Pixel Error**—Displays the running maximum tracking error and frame. The error is shown in pixel fractions, and gives the largest distance between any feature and the viewed position of its associated tracking object over all the frames matched. You can use this to give a general estimate of how good the match is and the frame to investigate if errors are problematic. The pixel
error display also interactively updates as you nudge tracker gizmos in Live Camera Match mode, showing the current maximum match distance for the camera; see Movie Stepper Rollout (page 2–676).

Note that this error might be exaggerated when you employ match point weighting, as this tends to distribute the errors toward the nonweight points.

**Show Errors**—Opens a text window containing a list of the maximum errors for each of the matched frames, so you can look over the whole set of match frames and identify which frames to check.

---

### Camera Tracker: Move Smoothing Rollout

Because the match-move algorithm is not always exact and is highly susceptible to field measurement error or feature tracking errors, and because the match for each frame is computed independently, the results can be "noisy," particularly if field of view is estimated. In match-move situations where the real camera performs smooth moves, it might be useful to filter the match results to eliminate this noise.

You use the Move Smoothing rollout to control and perform these smoothing operations after a match has been created.

#### Interface

**Channel To Smooth group**

Let you choose which parameter or set of parameters to smooth. You can choose to smooth the entire Rotation or all the Position tracks at once, or you can smooth individual parameters or axes.

- **Rotation**—Pan, Tilt, and Roll.
- **Position**—Dolly, Truck-H, and Truck-V.
- **FOV**—Camera FOV (field-of-view).
- **Pan**—Rotation about the local camera Z axis.
- **Tilt**—Rotation about the local camera X axis.
- **Roll**—Rotation about the local camera Y axis.
- **Dolly**—Movement along the local camera Y axis.
- **Truck-H**—Movement along the local camera X axis.
- **Truck-V**—Movement along the local camera Z axis.
Smooth Type group

**Straight line average**—Causes Move smoothing to generate a straight line average for each of the selected parameters. This is useful when you know a parameter is fixed, but don’t know its actual value. Examples might include field-of-view or vertical position. Use the camera matcher to initially estimate the parameter, then construct a straight line average fit and rematch the remaining parameters.

**Low pass filter**—Causes Move smoothing to apply a low-pass filter to the selected parameters, eliminating high-frequency noise.

**Smooth amount**—Implements smoothing using a Gaussian low-pass filter whose width and variance are controlled by the Smooth Amount spinner. Increase this value to increase the smoothing.

Smooth Range group

Controls the range of frames over which the smoothing will be performed.

**Match-Move Range**—Applies the smoothing to the range of animation frames specified in the Match Move rollout. This allows you to break up a match-moving job into several frame ranges. Use this to isolate and experiment on a troublesome range of frames, without disturbing other satisfactory frames.

**All Frames**—Applies the smoothing to all the keyframes in the selected parameters.

**Rematch After Smooth**—Controls whether a compensating match-move is performed after the filtering. If this is turned on, the parameters that were smoothed are disabled in the Match rollout and another match-move is performed. Performing this rematch again is advised because it adjusts the other camera parameters to compensate for the smoothing and often results in a smoother estimation for the unsmoothed parameters.

**Smooth**—Performs the move smoothing based on the smooth type, range, and amount settings. If this button is disabled, no current match camera is assigned.

Camera Tracker: Object Pinning Rollout

Utilities panel > Utilities rollout > More button > Utilities dialog > Camera Tracker > Object Pinning rollout

Object Pinning lets you use the 2D image feature tracking data to directly animate objects in the 3ds Max scene. This is useful for replacing moving features in the scene with 3D objects when the movement is approximately planar. After the tracking data is created you can use this function to do such things as synchronizing the movement of 3D objects with feature movements in the background movie. If the 3D objects directly cover the background features, they will appear to replace them. For example, you could take the video of a juggler juggling balls and replace the balls with 3D balls of fire or synchronize the movement of an animal’s head with a 3D jaw to create talking animal animations.

**Procedure**

**Example: To create a juggler juggling 3D balls of fire:**

This assumes you already have a video of a juggler. Otherwise, find a juggler and a video camera.

1. Load a video of a juggler.
2. Create tracker gizmos to associate with the juggling balls.
3. Use the Movie Stepper to track the gizmos.
4. Go to Object Pinning and choose the tracker.
5. Under Object To Pin, associate an object with a tracker. In this case, create a 3D ball of fire using fire or an animated map to generate the fire.
6. Adjust the Pin Range, and then click the Pin button to move the object to follow the tracker.

Interface

Choose Tracker—Shows all the current trackers as set up in the Motion Trackers rollout. Use this to select the tracker whose feature movements you will use to control the pinned 3ds Max object. The feature must have been tracked already over the frames you want to use, with the Track and/or Movie Stepper rollouts. Note that the accuracy of the pinning is determined by the accuracy of the match, so subpixel tracking is highly recommended.

Object To Pin—Lets you choose the object in 3ds Max scene for pinning and animating. By default the tracking object associated with the selected tracker is preloaded into this button. You can use this picker if you wish to pin a different object.

Pin Range group

Movie Start—The movie frame from which to start using tracked feature positions.

Animation Start—The frame in the 3ds Max animation at which to start keyframing the move of the pinned object.

Frame Count—The number of frames to animate. There must be enough tracked positions in the selected tracker to cover this number of frames.

Reset Ranges—Reloads the maximum frame number and count ranges into the above spinners from the current movie and 3ds Max scene settings.

Pin Space group

Let you select the plane of motion in which the keyframed pinning will occur.

Screen—Moves and ani mates the pinned object in the plane of the screen at its current depth in the scene. This is equivalent to dragging an object around in the Screen reference coordinate system in 3ds Max.

Grid—Moves and animates the pinned object in the plane of the currently active grid. This lets you set up an arbitrary plane of motion for the pinning by constructing a grid helper object in the desired place and making it the active grid. If you don’t have a grid helper set up and active, the pinning will occur on the 3ds Max Home Grid.

Pin Mode Group

Lets you choose between two different pinning modes: absolute and relative.

Absolute—Places and moves the pinned object exactly over the tracked feature. If combined with grid space, the object is also placed and moved directly on the active grid plane.
Relative—Leaves the pinned object at its current position in space and moves it so that its projected position relative to the tracked feature remains the same throughout the pinning frame range. This makes it possible to animate an object that you don’t want placed exactly over a feature, or to animate an object using several features in successive frame ranges. (For example, a computer generated jaw can track an ear for some frames, then a nose for others in a talking animal shot). If combined with grid space, the object is not moved onto the grid plane, but keeps its height above the grid and is moved parallel to it.

Pin—Performs the actual pinning, moves the object to follow the selected feature and places a keyframe at each frame in the pin frame range. As with the other keyframing operations in the tracker, you can undo a pin using the 3ds Max Undo function. You might also find it useful to perform keyframe reduction afterwards in Track View.

Camera Tracker: Troubleshooting
Feature Tracking Halts Immediately
If the feature tracker attempts to match the first couple of frames but halts immediately, check these steps:

1. One of the enabled error thresholds might be set too low. Perform a Check Status in the Batch Track rollout and look at the reports in the Tracking Error Review list. Also try disabling the thresholds in the Error Thresholds rollout one at a time and see if this fixes the problem. Adjust the problematic threshold as needed. You can also disable threshold checking altogether by turning off the Resample On Error check box in each of the trackers.

2. Make sure the search bounds box for each tracker is big enough to accommodate the frame-to-frame motion of the feature. This needs to be at least big enough to enclose the moved feature and the surrounding contrast area you’ve selected in the feature bounds box.

3. Make sure the scene objects are associated correctly with their trackers. You can verify this by checking the entries in the list at the top of the Motion Trackers rollout. If there is an object associated, you will see its name in the list entry, if not you will see “<no object>”. If you open a movie file for which you have previously set up trackers in the camera tracker before you open the associated 3ds Max scene, the objects won’t be associated with their trackers. You should make sure the correct 3ds Max scene is open then close and reopen the movie file in the Camera Tracker so that it can now find the scene objects.

4. If you have inadvertently swapped the scene objects for one or more pairs of trackers, the match-move can’t find a solution.

Repeated Match-Move Errors
If you get repeated camera match-move errors, here’s a list of things to check:

1. Make sure there are at least six features actively being tracked at the error frame and that at least two of them are a good distance out the plane of the others.

2. Check the tracker gizmos in the Movie window around the frame on which the error occurs to ensure that no obvious feature tracking errors exist.

3. If you’ve disabled any parameters in the Match section of the Match-Move rollout prior to a match-move, the camera being matched must be already set correctly in the scene for those parameters. For example, if you disable roll and FOV, you must already have set the camera to the correct FOV and roll orientation, either directly in 3ds Max, or as a result of a previous match-move. The matching algorithm uses all
the “fixed” camera parameters to compute the ones being estimated and simply won’t work if they’re fixed at incorrect values.

4. You may know that some of the camera parameters don’t vary during a match sequence, but you aren’t sure of their values. One approach to this situation is to enable all parameters for an initial match and then apply a straight-line average filter to them in the Move Smoothing rollout. This automatically disables them in the Match section and with luck sets them at a good estimate of the fixed position.

---

**Dynamics**

Utilities panel > Utilities rollout > More button > Utilities dialog > Choose Dynamics.

The term *dynamics* refers to a system of controls that generate keys to produce animation that simulates real-world physics. For example, using standard keyframing techniques to animate a bouncing ball, you create keys that move the ball down to the floor, squash the ball, move the ball back up, and so on.

Using a dynamics system, you assign physical properties to the ball and the floor (such as friction or amount of bounce), specify which object will collide against another object (for example, the ball with the floor), place an effect (such as gravity), in the scene, and then calculate a solution over a range of frames. The result is a number of keys that produce an animation in which the ball drops due to the gravity effect, collides with the floor and reacts naturally based on its surface characteristics.

Note: As of 3ds Max 5, the preferred tool for dynamics simulation is reactor, available from the Utilities panel. The reactor plug-in lets you control and simulate complex physical scenes with ease. reactor supports fully integrated rigid and soft-body dynamics, cloth simulation, and fluid simulation.

**Objects and Space Warps Used to Create Dynamics Simulations**

A very basic simulation would involve creating a sphere and a gravity space warp, adding the sphere to a new simulation, assigning gravity as an effect on the sphere and solving the simulation. The result is that the sphere falls under the force of gravity.

You can use dynamics objects (page 1–395), dynamics space warp deflectors (PDynaFlect (page 2–81), SDynaFlect (page 2–85), and UDynaFlect (page 2–86)), and space warp forces such as Gravity (page 2–73) and Wind (page 2–75) to add complexity to a simulation. You can use a particle stream from a particle emitter as a force on an object: the particles can collide with and be deflected by the object, as well as move it. You can attach special dynamics objects to objects, such as Spring (page 1–400) to simulate the effects of a spring.

You can combine effects: Wind, gravity, a spring object, collision, particle deflection and collision, as well as surface properties such as friction, can all work on an object in a simulation. For a full understanding of what dynamics can do, explore this topic and areas of 3ds Max that pertain to dynamics.

**Dynamics-Specific Areas in 3ds Max**

The Dynamics Utility (this topic)

The Dynamics Utility is the main control center for dynamics simulations. You specify which objects are used in the simulation, what their interactivity is with each other and with the effects in the scene. The simulation is then “solved,” generating the keyframes.
The effects of collisions between objects depend on the velocity of the objects and their properties. For collision to work between two objects, each object must have the other object assigned for collision. For example, when bouncing a ball, both the floor and the ball are assigned collisions.

**The Material Editor:** The *Dynamics Properties rollout (page 2–1479)* in the Material Editor lets you assign the dynamics properties to the surface of an object, like friction and bounce. Using a multi/sub-object material, you can have different surface properties at the face level of any object.

*Note:* You can override material surface dynamics properties with controls on the *Edit Object dialog (page 2–696)* in the Dynamics utility.

**Dynamics Objects, Particles and Dynamics, Dynamics Interface:** Special objects like Spring and Damper, Space Warp forces like Gravity and Wind, as well as Space Warp deflectors like PDynaFlect can all influence a dynamics simulation. You must create these objects and space warps first in other areas of 3ds Max before you can use them in a dynamics simulation. See the following topics for details on their creation and use:

- Create panel > Geometry > Dynamics Objects *(page 1–395)*
  
  You can use the Spring and Damper objects for dynamics effects.

- Create panel > Space Warps (page 2–55) > Particles and Dynamics.
  
  Effects (forces) are special space-warp objects that emulate natural phenomena, such as wind or gravity. In a dynamics simulation, you must place gravity in the scene if you want the objects in your simulation to fall.

- Create panel > Space Warps (page 2–55) > Dynamics Interface.
  
  The Dynamics Interface space warps can cause particles to deflect from and affect an object in a simulation.

**Combine Keyframed Objects in a Simulation:**
Keyframe an object and have it interact with other objects in a dynamics simulation by turning on the *This Object is Unyielding* check box in the Edit Object dialog for the keyframed object. Objects can bounce off of a keyframed sphere for example.

**Dynamics Controller:** When a Dynamics simulation is solved, a new list controller is created that holds both the generated dynamics keys and the original keys. This allows you to restore your original keys, if necessary. Undo is not supported by Dynamics.

For example, if a sphere is bouncing in a Dynamics simulation, and the sphere already contains position keys from a previous animation, the following tracks display in Track View:

**Transform**

- Position
  - Dynamic Position Controller
  - Old Position
- Rotation
  - Dynamic Rotation Controller
  - Old Rotation

**Procedures**

**Example: To create a basic simulation of bouncing boxes:**

1. Create a thin box in the Top viewport.

   Have the box almost the same height and width as the viewport. This will act as the ground plane.

2. In the Front viewport, create six small boxes above the "ground" box.

   Position some of them to collide with each other when they fall.
3. On the Create panel > Space Warps > Particles and Dynamics > Object Type rollout, click Gravity.

4. Drag in the Top viewport to create a Gravity gizmo.

5. On the Utilities panel, click Dynamics.

   Dynamics00 appears in the Simulation Name field.

7. Click Edit Object List.

   The Edit Object List dialog displays.

8. Select all the boxes in the dialog and click the > button, then click OK.

   All the objects are moved to the Objects in Simulation list on the right side of the dialog.

   The Edit Object dialog displays.

10. In the list under Object, choose Box01.

11. Turn on Dynamics Controls group > This Object is Unyielding.

12. Click Ok to close the Edit Object dialog.

   The "ground" box won't move when the other objects collide with it.

14. Click Assign Global Effects, select Gravity in the dialog and click > (right arrow), then click Ok.

   This assigns gravity to all objects in the simulation.

15. On the Dynamics rollout, in the Collisions group, turn on Global Collisions.

16. Click Assign Global Collisions, select all the boxes in the dialog and click > (right arrow), then click OK.

   Collisions are active for all the boxes.

17. Turn on Update Display with Solve, and then click Solve.

   In the viewports the objects fall and collide with each other and the ground plane.

18. Turn on the Auto Key button, move the time slider to frame 15, and then select and move the "ground" box upward along the Z axis.

   The ground will "move" during the simulation.

19. Click Solve.

   The keyframed "ground" box moves up and collides with the boxes. The ability of a keyframed object to be part of a simulation is one of the useful features in 3ds Max. You could use this capability to strike a ball with a bat, for example.

   For further experimentation, create a spring object in Create panel > Geometry > Dynamics Objects and attach the ends of the spring object to two of the boxes and then solve the simulation. The spring will stretch and follow the bouncing boxes.

   You can use the space warps in Create panel > Space Warps > Dynamics Interface, such as SDynaFlect (Spherical Dynamics Deflector) to cause a particle stream to "push" an object in a dynamics simulation.

   **To remove the dynamics tracks and restore the original animation tracks in Track View:**

   When you solve a dynamics simulation, 3ds Max creates a list controller that holds both the generated dynamics keys and the original keys. This lets you easily restore the original keys. Undo is not supported by Dynamics.

   To layer simulations, reverse this method. In other words, after you've solved the first simulation, copy its controllers to the old tracks, and then set up the next level of the simulation. The new simulation will base its actions on the previous one instead of overwriting it, as it normally does. You
can repeat this as many times as you like to layer simulations \textit{ad infinitum}.

Since Undo is not supported by Dynamics, you can also use Hold and Fetch in its place.

1. In Track View, open the Position track for an object animated by a dynamics simulation.
2. Select the Old Position track, and click Copy Controller on the Track View toolbar (the second button from the left).
3. Select the Position track (the parent), and click Paste Controller (to the right of Copy Controller).
4. Click OK in the Paste dialog.
   The two sub-tracks and the Position parent track are replaced by a single Position track containing the original keys that were in the Old Position track.
Repeat the above steps with the Rotation track.

To set up dynamics:

1. Assign materials to the objects included in the simulation and adjust the surface characteristics in the Dynamics Properties rollout of the Material Editor. (For a bouncing ball, you’d use this to create a rubber-like surface.)
2. If you’re using a linked hierarchy, set the Move and Rotate locks in the Hierarchy/Link Info panel to limit the motion and rotation of the linked objects.
3. Create space warp effects in the scene where needed. (For a bouncing ball, you’d need a Gravity space warp.)
4. Use the Dynamics utility to create a new simulation. Specify which objects are included in the simulation, which effects influence which objects, and which objects should collide with which. (For the bouncing ball, the ball and the floor are in the simulation because one collides with the other. You assign the ball the floor to collide with each other, and assign the gravity effect to the ball.)
5. Use the Dynamics utility to specify the range of frames to which keys will be generated, and to calculate the animation and generate the keys. (In the case of a bouncing ball, a number of position and rotation keys are generated for the ball.)
6. Play the animation to see if the effect is what you were looking for. If one or more objects fly off into space, or move through objects they should have bounced off, it’s likely that you need to increase the Calc Intervals Per Frame value.

To set up dynamics:

1. Assign materials to the objects included in the simulation and adjust the surface characteristics in the Dynamics Properties rollout of the Material Editor. (For a bouncing ball, you’d use this to create a rubber-like surface.)
2. If you’re using a linked hierarchy, set the Move and Rotate locks in the Hierarchy/Link Info panel to limit the motion and rotation of the linked objects.
3. Create space warp effects in the scene where needed. (For a bouncing ball, you’d need a Gravity space warp.)
4. Use the Dynamics utility to create a new simulation. Specify which objects are included in the simulation, which effects influence which objects, and which objects should collide with which. (For the bouncing ball, the ball and the floor are in the simulation because one collides with the other. You assign the ball the floor to collide with each other, and assign the gravity effect to the ball.)
5. Use the Dynamics utility to specify the range of frames to which keys will be generated, and to calculate the animation and generate the keys. (In the case of a bouncing ball, a number of position and rotation keys are generated for the ball.)
6. Play the animation to see if the effect is what you were looking for. If one or more objects fly off into space, or move through objects they should have bounced off, it’s likely that you need to increase the Calc Intervals Per Frame value.

To reduce the number of keys generated by the Dynamics utility:

When you solve a dynamics simulation, Position and Rotation keys are generated at every frame of the specified range for every object affected in the simulation. Not only does this result in an excess of keys for later editing, but it can increase the size of the .max file tremendously. The following steps show how to reduce the number of keys using Track View.

1. After solving the simulation, check the animation to make sure it’s what you want, and then save that version of the scene.
2. Deselect every object in the scene.
3. In the Dynamics panel > Objects in Simulation group, click the Select Objects In Sim button.
   All objects included in the simulation are selected.
4. Open a Track View window, and then set its filter to show Animated Tracks Only and Selected Objects Only.
5. Right-click the top object in the Hierarchy list (Objects), and choose Expand All.
   Track View now shows all tracks in the simulation that have keys.
6. Go to Edit Time display mode and select all of the tracks containing keys (or right-click over the hierarchy, and choose Select All).

7. Double-click any key to select all keys in all tracks.

8. Click the Reduce Keys button, set the Threshold to what you want, and then click OK. All selected keys are reduced.

9. Save the reduced version of the scene either under a new name, or by replacing the original file.

To use linked hierarchies in a simulation:

When linked hierarchies are included in your simulation, you must set locks for the children in the simulation to confine the dynamics results to specific axes. Do this on the Hierarchy panel > Link Info > Locks rollout (page 2–500).

The Locks rollout contains three rows of check boxes affecting the XYZ axes of the three possible transforms: Move, Rotate, and Scale. The Scale transforms are ignored, and only the Move and Rotate locks are used. When a check box is turned on, that axis of the specific transform is locked.

When you manipulate a forward-kinematics hierarchy directly using the Move or Rotate tools, you might not bother with the Link Info locks, because you can specify axis constraints using the X, Y, Z, and XY buttons in the toolbar. However, when you use that same hierarchy in a dynamics simulation, where there are several forces at work (gravity, wind, collisions), the only thing that maintains the linkage between the objects is the locks you set in the Link Info > Locks rollout. As a result, no matter what combination of Move and Rotate locks you use, you’ll always want at least one Move lock in place, or your objects won’t really be linked.

The following lists all of the combinations of Move and Rotate locks that make sense within a dynamics simulation, and the effect on the link of such combinations. An asterisk (*) indicates those combinations that are more typically useful.

The format of this list is as follows:
X=check box on.
O=check box off.

One group of settings is made up of the three Move check boxes over the three Rotate check boxes. Here’s an example:
XXO=X and Y Move check boxes on, and Z off.
OXO=Y Rotate check box on, and X and Z off.

1. **1 Move Lock**: Turn on any single Move. (This is like a long pin sliding in a loose, long slot.) The joint can transmit force in one direction only. The objects can slide with respect to each other in two directions and rotate freely.

2. **2 Move Locks**: Turn on any two Moves. (This is like a sliding ball joint; a freely rotating joint at the end of a sliding shaft, which can slide and rotate in a hole.)

3. **3 Move Locks**: Turn on three Moves. (This is like a ball joint, or the theoretical "pin joint" of the statics and dynamics texts, in that it transmits any force but never transmits any torque.)

4. **1 Move + 1 Rotate (unique)**: Turn on any one Move and any one Rotate, but not in the same column. (This is like two long pins, parallel, sliding in a single long slot.) The joint can transmit force in one direction only and restrain rotation about the axis of the "pins." This combination is of limited application.

5. **2 Moves + 1 Rotate (matching)**: Turn on two Moves, plus one Rotate turned on that’s in the same column as one of the selected Moves. (This is the same as 1 Move + 1 Rotate, above, except that the pins can no longer slide vertically in their slot.) If the assembly rotates
so that one pin travels further into the slot, the other must ride higher in the slot. This is of limited application. The possible check box combinations are: XXO XOX XOX OXX OXX OXX OXX OXX OXO

6. * 2 Moves + 1 Rotate (complementary): Turn on two Moves, plus one Rotate that’s not in the same column as any of the selected Moves. (This is a sliding universal joint like the splined output shaft between the automatic transmission of a rear-drive car and the drive shaft.) It can transmit torque and constrain translation in two directions, both orthogonal to the axis of rotation. The possible check box combinations are: XXO XO XOX OXX OXX OXX OXX OXO

7. 3 Moves + 1 Rotate: Turn on three Moves plus one Rotate. (This is a universal joint without the sliding.) It’s typical of automotive applications where the rear axle is located with the trailing drive shaft. This is an uncommon application.

8. * 1 Move (complementary) + 2 Rotates: Turn on one Move that’s complementary to two Rotates. (This is like a hockey puck on ice.) The joint can slide anywhere on a plane, but cannot fall or tip, and it cannot leave the surface of the plane. The possible check box combinations are: XOO OXO OOX OXX OXX XOX

9. 2 Moves (one complementary) + 2 Rotates: Turn on two Moves, one of which is complementary to one of the two Rotates that are selected. (This is like a hockey puck with a nail through it, and the nail is sliding along a groove in the ice.) It’s free to travel in one direction, and to rotate about an orthogonal axis. One possible check box combination is: XXO XO

10. * 2 Moves + 2 Rotates (matching): Turn on two Moves and two matching Rotates. This results in a sliding axle (a shaft that can both slide in and out of a hole, and rotate with the hole). The clear Move and Rotate axis specifies the axis along which the joint can slide and rotate. The possible check box combinations are: XXO XOX OXX XOX OXX OXX

11. * 2 Moves + 3 Rotates: Turn on two Moves and all three Rotates. (This is a prismatic or sliding joint.) The joint transmits no torque, and force in only one direction. You can use this in conjunction with the Push effect to make a hydraulic cylinder. The one clear Move specifies the axis of movement.

12. * 3 Moves + 2 Rotates: Turn on all three Moves, and any two Rotates. This is an axle (the most common type of joint.) The one clear Rotate specifies the axis of rotation.

13. All Locked: All six check boxes are on. This is a completely rigid joint.

**Interface**

**Dynamics rollout**

Contains all of the surface dynamics controls.
Simulation Name—Displays the name of the current simulation. You can edit the name to rename any existing simulation.

You can create any number of simulations in your scene. Each must have a unique name and is stored in the .max file. For example, you might have a simulation named Bouncing Ball that bounces a ball down a flight of stairs, while another simulation named Paper Airplane flies a paper airplane across the room.

List—Displays the name of the current dynamics simulation, and lists all simulations in the scene. If the list contains two or more simulations, choose one from the list to make it current. All remaining panel settings are specific to the current simulation.

New—Creates a new simulation. Its name consists of the word "Dynamics" appended by a number, starting with 00. This number is incremented by one for each new simulation.

Remove—Deletes the current simulation. Dynamic simulations can use a lot of memory. Removing old or unused simulations reduces the size of your .max files. When you remove a simulation, all timings and other settings are deleted. However, any keys generated by the simulation remain.

Copy—Creates a duplicate of the current dynamics simulation. All of the settings are identical to the original simulation, with the addition of “01” appended to the name.

Objects in Simulation group

Lets you add and remove objects from the simulation, and edit the properties of objects in the simulation.

Edit Object List—Displays the Edit Object List dialog (page 2–700), which lets you specify which scene objects are to be included in the simulation.

Edit Object—Displays the Edit Object dialog (page 2–696).

The Edit Object dialog is the main interface for object dynamics attributes. Use this dialog to set collisions, effects, surface properties and mass for each object in the simulation.

Select Objects in Sim—Adds all objects in the simulation to the current selection set. One use for this function is to bring selected objects into Track View for further manipulation, keyframe reduction, and so on.

Effects group

Specifies which effects are included in the dynamics calculation.
Effects by Object—Only effects assigned to specific objects with the Edit Object dialog > Assign Object Effects button are considered in the calculation.

Global Effects—Only effects included in the Assign Global Effects dialog (accessed by clicking the button of the same name) are included in the calculation.

Assign Global Effects—Displays the Assign Global Effects dialog.

Select effects (space warps) in the list on the left and use the > button to move them to the list on the right. Effects thus chosen affect all objects in the simulation except unyielding ones.

The Assign Global Effects dialog functions similarly to the Edit Object List dialog (page 2–700).

Collisions group

Specifies which collisions are included in the dynamics calculation.

Collisions by Object—Collisions assigned to specific objects through the Edit Object dialog > Assign Object Collisions button are included in the calculation.

Global Collisions—Collisions assigned in the Assign Global Collisions dialog (accessed by clicking the button of the same name) are included in the calculation.

Assign Global Collisions—Displays the Assign Global Collisions dialog.

Select the objects in the list on the left and use the > button to move them to the list on the right. All objects thus chosen collide with each other in the simulation.

The Assign Global Collisions dialog functions similarly to the Edit Object List dialog (page 2–700).

Solve group

Update Display w/ Solve—Displays each frame of the solution in the wireframe viewports during the calculations. This slows down the calculation process.

Solve—Calculates the dynamics solution, generating keys over the range of frames specified in the Timing area. A progress bar appears in the status/prompt line. Press ESC to cancel the calculation.

Note: You cannot undo the generation of a dynamics simulation solution. If there’s a chance you might want to restore the scene to its state prior to the solution, either save (page 3–390) the scene or use Hold (page 1–95) before solving it.

Timing and Simulation rollout

Lets you specify the range included in the calculation, how IK is included in the simulation, and what the air density is for the simulation.
Timing group
Controls how keys are generated over time.

Start Time—Specifies the first frame to generate keys, which is the first frame to be considered for the solution. Default=0.

Tip: If you set a start time that’s later than a keyframe-animated object’s last animation frame, you may get unexpected motion during the interim frames. For example, if you animate a box’s position from frames 0 to 10, and then use the box in a dynamics simulation that starts at frame 20, the box will move between frames 10 and 20 because of the Bezier controller’s default interpolation. To avoid this, before solving the simulation, set the last animation keyframe’s Out tangent type to Linear or Step; see Bezier Controllers (page 2–310). Alternatively, set the last key of the keyframed "input motion" after the start time of the simulation, or set a start time before the last key.

End Time—Specifies the last key considered for the solution. This spinner is set to the last frame of the active segment (page 3–904) when you create a new simulation. For example, if your active segment ends at frame 200, when you click New to create a new simulation, End Time is set to 200.

Calc Intervals Per Frame—Specifies how many calculations are performed for each frame of the simulation time range. Range=1 to 160.

Finding the right number for this spinner is a matter of experimentation. As a general rule, the faster things are moving in the simulation, the higher you should set this value.

Note: If you find that some objects aren’t colliding properly with others (they’re going through them), increase the Calc Intervals Per Frame value.

Keys Every N Frames—Specifies the frequency with which keys are generated, per object. If this were set to 2, keys would be generated in every other frame.

Warning: When you reduce the key count by increasing this setting, important information can be lost. For example, if a collision occurs on frame n, the Dynamics utility normally sets keys at frames n, n+1, and n-1. But if you’ve set Keys Every N Frames to 2, a keyframe for the impact itself might not be generated, while keys for the sudden reversal of motion would be generated on either side of the (missing) impact. Thus, the motion controller is left to interpolate motion in a region where the motion should be sharply defined. When this happens, motion can be incorrect and the remainder of the solve is affected. In the aforementioned example, a key describing the impact is lost and the motion controller interpolates motion so that objects that should collide actually intersect, ruining the simulation.

Time Scale—Slows down or speeds up the overall effect of the simulation. It applies a linear scale.
factor to the outside forces affecting each object (gravity, wind, and so on).

The default value of 1 results in normal speed. You can scale down the simulation (make it slower) by using values below 1 (from 0.1 to 1), and you can scale up the simulation (make it faster) by using values greater than 1 (from 1 to 100). If you speed up your simulation and objects begin to behave incorrectly (going through objects, for example), increase the Calc Intervals Per Frame value to compensate.

Simulation Controls group
Relates to IK settings and the transfer of momentum.

Use IK Joint Limits—Uses the current IK joint limit settings as constraints for hierarchies in the simulation.

Use IK Joint Damping—Uses the IK damping settings as constraints for hierarchies in the simulation.

Air Resistance group

Density percent—Sets the air density in the simulation. A setting of 100 is the air at sea level. A setting of 0 is a total vacuum.

When anything moves, it hits air resistance (except in space). The faster it moves, the higher the relative air resistance with the square of the speed. Thus, air resistance imposes an upper limit on the speed of things that are falling with gravity, and also makes objects tumble due to the effect of air resistance on each face of the object.

Close—Closes the Dynamics utility.

Dynamics Properties Material Editor rollout

The three spinners in the Dynamics Properties rollout in the Material Editor let you specify surface properties that affect the animation of an object upon collision with another object. If there are no collisions in your simulation, these settings have no effect.

Because the Dynamics Properties rollout is available at the top level of any material (including sub-materials), you can specify different surface dynamic properties for each face in an object. There are also controls in the Dynamics utility that let you adjust the surface properties at the object level, but only the Material Editor lets you alter the surface properties at the sub-object level (through use of a Multi/Sub-Object material).

As a default, the values in the Dynamics Properties rollout provide a surface that’s similar to Teflon-coated hardened steel. This is with values of Bounce Coefficient equal to 1; with both Static Friction and Dynamic Friction set to 0.

Bounce Coefficient—Determines how far an object bounces after striking a surface (the higher the value, the greater the bounce.) A value of 1 represents a bounce in which no kinetic energy is lost.

Static Friction—Determines how difficult it is for an object to start moving along a surface (the higher this value, the more difficult the movement). If something weighs 10 pounds and sits on Teflon (a static friction of near zero), it takes almost no force to make it move sideways. On the other hand, if it sits on sandpaper, then the static friction might be very high, around .5 to .8.
Sliding Friction—Determines how difficult it is for an object to keep moving over a surface (the higher this value, the more difficult for the object to keep moving). Once two objects begin to slide over one another, static friction disappears and sliding friction takes over. Generally, sliding friction is lower than static friction due to surface tension effects. For example, once steel starts sliding over brass (a value of static friction that might run from .05 to .2), the sliding friction drops to a significantly lower value: .01 to .1.

Edit Object Dialog

Utilities panel > Utilities rollout > More button > Dynamics > Dynamics rollout > Edit Object button > Edit Object dialog

The Edit Object dialog is the main interface for setting dynamic properties for any object in the simulation. You assign dynamics properties one object at a time. Select an object in the list under Object, and then set that object’s parameters. For example, you can cause the object to be affected by gravity or wind, and specify collisions with other objects.

Interface

Object—Displays the name of the object for which you’re setting the dynamic properties. All settings in the Edit Object dialog affect the object listed here. To change the object you’re affecting, open the list, and choose from a list of all objects assigned to the simulation.

Dynamic Controls group

Use Initial State—When turned on, the simulation solves for the motion, energy, and momentum of the object at the simulation’s starting frame (specified in the Start Time spinner in the Time and Simulation rollout > Timing group.) If Use Initial State is turned off, the object is assumed to be sitting motionless at the starting frame. The Dynamics utility overwrites keys. Either the object’s keys are clocked with the simulation, or it’s not moving (or both). If you don’t solve for the initial state, the object’s keys are interpolated at the instant the simulation starts and all subsequent motion comes from the interaction of the simulation itself.

This Object is Unyielding—Lets you use keyframe-animated objects in dynamics simulations. Objects with this option turned on are immovable relative to other objects that collide with them, but can be animated (keyframed).

You can animate objects with this option turned on by themselves or as part of a keyframed hierarchy. For collisions, objects with Use Initial State turned on cannot move objects with This Object is Unyielding turned on.

Move Pivot to Centroid—When this button is on (green) and you exit the Edit Object dialog by clicking OK, the object’s pivot point is moved to its center of mass. Having the pivot aligned with the center of mass speeds up the dynamics calculation and makes manual keyframing of the objects appear more natural. However, if the pivot point is already positioned as part of a linked hierarchy,
turning on Move Pivot to Centroid will alter the positioning of your hierarchical linkage.

**Load/Save Parameters Sets group**
Saves the current Edit Object parameter settings, or loads previously saved parameter settings. You can use these controls to save the settings for one object, and then apply them to another object.

**Set Name**—Accepts a new name for a parameter set. Click Save to save the parameter set with this name.

**Available Parameters Sets**—Lists previously saved parameter sets.

**Load**—Loads the selected parameter set.

**Save**—Saves the named parameter set. The saved parameter sets appear in the list.

**Delete**—Deletes the selected parameter set.

**Assign Effects/Collisions group**
Let you specify which effects in the scene will affect the current object, or which objects in the scene can collide with the current object.

**Assign Object Effects**—Displays a subdialog that lets you specify which effects in the scene will affect the current object. The dialog consists of two list windows. All effects (typically space warps) in the scene are listed in the window on the left. Select effects in the list, and then click the > button to transfer the highlighted effects to the window at right.

The Assign Object Effects dialog functions similarly to the *Edit Object List dialog* (page 2–700).

**Assign Object Collisions**—Displays a subdialog that lets you choose which objects in the scene are considered for collision with the current object. This dialog works the same as the Assign Object Effects dialog, except that it lists only objects in the scene.

**Recalculate Properties group**
Specifies when to recalculate the properties of an object that changes over the course of the animation. Specifically, the properties refer to the mass moment of the object. The mass moment of an object can be defined as the measure of how
the mass in an object is distributed with respect to the center of mass of that object. Altering the mass moment changes the way an object responds to torque. If your object is changing shape over time, and you want to take this into account for the simulation, you should recalculate the properties.

**Never**—No calculation is performed beyond the first calculation for the dynamics solution.

**Every Frame**—The object’s properties are recalculated for every frame.

**Every Calc Interval**—The object’s properties are recalculated at each “Calc Interval.” You set the Calc Interval (interval of calculation) in the Time Parameters rollout; it specifies how many calculations are performed for each frame of the simulation time range.

**Material Editor Physical Properties group**

Three of an object’s physical properties are taken by default from its material: bounce, static friction, and sliding friction; see *Dynamics Properties Rollout* (page 2–1479). Use these settings in this group to accept or override the material’s dynamics properties.

**Bounce**—Specifies how far the object bounces after collision. Available only if Override Material Bounce is on.

**Override Material Bounce**—Enables the Bounce spinner when you want to use a specific value that’s different than that assigned by the object’s material. When using a multi/sub-object material, you can assign different Bounce values to the sub-materials, and thus to different faces of an object. But if you use an override value, it affects the whole object only.

**Copy to Object’s Material**—Copies the value in the Bounce spinner to the material assigned to the object.

**Static Friction**—Specifies how hard it is to start moving on a surface. Available only if Override Material Static Friction is on.

**Override Material Static Friction**—Enables the Static Friction spinner when you want to use a specific value that’s different than that assigned by the object’s material. When using a multi/sub-object material, you can assign different Static Friction values to the sub-materials, and thus to different faces of an object. But if you use an override value, it affects the whole object only.

**Copy to Object’s Material**—Copies the value in the Static Friction spinner to the material assigned to the object.

**Sliding Friction**—Sliding friction determines how hard it’s for an object to keep moving over a surface. Available only if Override Material Bounce is on.

**Override Material Sliding Friction**—Enables the Sliding Friction spinner when you want to use a specific value that’s different than that assigned by the object’s material. When using a multi/sub-object material, you can assign different Sliding Friction values to the sub-materials, and thus to different faces of an object. But if you use an override value, it affects the whole object only.

**Copy to Object’s Material**—Copies the value in the Sliding Friction spinner to the material assigned to the object.

**Physical Properties group**

Provides controls that specify the physical properties of the current object.

**Density**—Specifies the density of the object in grams per cc. A setting of 1 is the equivalent of water, and useful for anything wooden, plastic, or organic. The more dense an object, the slower it will react to forces. There is a direct relationship between density and mass, so when you alter the
Density setting, the Mass value changes (when its automatic value is not overridden).

**Mass**—Technically, mass is the measure of how many subatomic particles are in an object. In 3ds Max, it’s calculated as a result of density times volume. Mass can be the resistance to acceleration given a constant force. The greater the mass, the more resistance. The Mass value, when not overridden, is derived from the density and volume, and the volume, when automatically calculated, is affected by the Calculate Properties Using option.

**Override Automatic Mass**—Enables the Mass spinner so you can specify the object’s mass. When you override the automatic value, the Mass value is no longer affected by the Density or Volume values.

Mass is affected by the Calculate Properties Using options.

**Volume**—The volume of the object, measured in cubic centimeters. When automatically calculated, this value depends on the option chosen under Calculate Properties Using.

**Override Automatic Volume**—Enables the Volume spinner so you can specify the object’s volume. When you override the automatic Volume value, it’s no longer affected by the Calculate Properties Using options, and it no longer affects the Mass value.

**Calculate Properties Using options**

Specifies the type of geometry the simulation will use to calculate the mass, the volume, and the mass moment. When the Mass and Volume values are automatically calculated (their overrides are turned off), changing these options affects the volume, and thus the mass.

**Vertices**—Treats an object as a "point cloud," or a collection of vertices without segments. Each vertex is given a mass of 1 gram, but the object itself has no volume.

**Surface**—Treats the object as a hollow shell whose thickness is 1 centimeter. The mass is derived from the surface area and the 1-centimeter thickness, but the object has no volume.

**Bounding Box**—A bounding box surrounding the extents of the object is used to calculate both the volume (of a solid bounding box) and the mass (based on the volume).

**Bounding Cylinder**—Similar to the Bounding Box option, except that a bounding cylinder is used, whose Z height axis is aligned with the local Z axis of the object.

**Bounding Sphere**—Similar to Bounding Box, except that a bounding sphere is used.

**Mesh Solid**—The geometry of the object is used to calculate both the volume and the mass, according.

**Property Estimate Resolution options**

Available only when the Mesh Solid option is chosen. The Property Estimate Resolution settings affect the accuracy with which the mass moment is calculated. This determines how accurately the rotation of the object responds to torque.

**Grid**—A sample grid is used to calculate the mass moment. The smaller the cells in the grid, the more accurate the calculation. The grid cells are measured in centimeters, regardless of the current display unit.

**Override Automatic Resolution**—Lets the Dynamics utility automatically set the grid size based on the complexity and size of the object. In addition, the lowest value that will be automatically calculated is plugged into the Grid spinner (which is also unavailable). If you want to specify your own grid value using the Grid spinner, but want some idea of where to start, turn off Automatic Resolution and then turn it back on again.
Edit Object List Dialog

Utilities panel > Utilities rollout > More button > Dynamics > Dynamics rollout > Edit Object List button > Edit Object List dialog

The Edit Object List dialog lets you select the objects to include in a dynamics simulation. Highlight objects from the Objects in the Scene list on the left, and then click the > button to place them in the Objects in the Simulation list on the right side of the dialog.

The Exclude and Include option buttons above the right window determine whether the items listed are excluded from or included in the simulation.

Note: All the selection and inclusion dialogs in the Dynamics Utility are displayed and function similarly.

Interface

**Objects in the Scene**—To add scene objects to the simulation (assuming Include is chosen), select objects from the list on the left, then use the > button to move them to the list on the right.

**Search Field**—The edit box above the Scene Objects list lets you search for object names by entering names that use wildcards. For example, searching for "sphere*" finds all objects whose names start with "sphere".

**Objects in the Simulation**—To exclude objects from the simulation (assuming Include is chosen), select objects from the list on the right, then use the < button to move them to the list on the left.

**Exclude/Include**—Choose whether the simulation will exclude or include the objects named in the list on the right. If you choose Exclude, only objects in the list on the left are included in the simulation.

**All/None/Invert**—Affect the list on the left. All selects all objects, None deselects all objects, and Invert selects unselected objects and deselects selected objects.

**Display Subtree**—Turn on to indent the list according to the object hierarchy.

**Case Sensitive**—Turn on to use case sensitivity when searching for object names.

**Select Subtree**—Selects all objects in a hierarchy at the level you click and below.

**Selection Sets**—Displays a list of named selection sets. Choosing a selection set from this list selects those objects in the Scene Objects list.

**Clear**—Clears all entries from the Exclude/Include list on the right.

Skin Utilities

Utilities panel > More button > SkinUtilities

Skin Utilities provide a method for copying skin data (envelopes and vertex weights) from one model to another. Skin Utilities work by embedding the skin data in a copy of the source mesh, then using the object copy to map the data onto the target mesh.
To use Skin Utilities, you must have two meshes to which the Skin modifier (page 1–791) has been applied, both in the current scene. You must have already assigned bones to the Skin modifier for both meshes.

Note: Skin Utilities work by matching bones from one character to another, so the task of copying the skin data will be greatly simplified if you name the bones in each mesh with similar naming conventions.

**Procedure**

**To use Skin Utilities:**

1. Load a scene that contains two skinned meshes, one from which you want to extract the skin data, the other to which you want to paste it.
2. Select the source mesh, the mesh with the correct envelopes and vertex weights.
3. Choose Utilities panel > More button > Skin Utilities.
4. Click Extract Skin Data to Mesh.
   
   A new object is created, identical to the selected object. This is a new mesh with all envelope-assigned and manually-assigned vertex weights “baked” into the mesh. The object is named with the prefix SkinData_ followed by the same name as the original object.
5. Move the skin data mesh on top of the mesh to which you would like to paste the skin data, so the two meshes are coincident.
6. If necessary, adjust the skin data object at the Vertex sub-object level to make it fit the other mesh as closely as possible.
7. Select both the skin data object, and the object to which you want to paste the data.
8. Click Import Skin Data From Mesh.
   
   The Paste Skin Data dialog appears.
9. Match up the bones by highlighting one on each side of the dialog, and clicking the left arrow to move the target bone to its match on the left side.
   
   You can also highlight several bones on each side at once, and click the left arrow to move them all over at the same time. Only bone pairs on the left side of the dialog will be pasted.
10. If the meshes’ vertices do not match exactly, set the Interpolation method to Match by Face, and increase the Threshold to a unit value that will allow the meshes’ faces to match up.
11. Click OK to paste the vertex weights and close the dialog.
12. Delete the skin data mesh.

**Interface**

- **Extract Skin Data to Mesh**—Extracts the skin data from the selected mesh and embeds it in a new mesh named SkinData_ followed by the original object name.

   Note: The skin data is stored in channels. To see the data, select the SkinData_ mesh and use the Channel Info Utility (page 2–1738).

- **Import Skin Data From Mesh**—Opens the Paste Skin Data dialog. Before clicking this option, you must select the SkinData_ mesh and the mesh to which you want to paste the data.
To use the Paste Skin Data dialog, highlight matching Target Bones and Source Bones, and click the left arrow to match them. Only matched sets of bones listed under Target Bones will be mapped when you click OK.

**Target Bones**—Lists target bones available for matching, and lists matches moved from the Source Bones listing with the left arrow.

**Source Bones**—Lists source bones available for matching.

**Add**—Adds removed bones back to the source or target list.

**Remove**—Removes highlighted bones from the source or target list.

**Remove Suffix**—If bone names end with an underscore followed by text, this removes the suffix from the displayed bone names from the underscore to the end of the name. Use this option to remove suffixes and make source and target bone names match, which will allow you to use the Match by Name option.

**Remove Prefix**—If bone names start with text followed by an underscore, this removes all characters from the displayed bone names up to and including the underscore. Use this option to remove prefixes and make source and target bone names match, which will allow you to use the Match by Name option.

**Left Arrow**—Matches highlighted target bones to highlighted source bones. The source bone name is moved to the left side of the dialog, where it follows the target bone name. You can also match more than one source bone to a single target bone by highlighting the target bone and the source bones and clicking the left arrow. When you click OK, only the matches listed on the left side of the dialog will be mapped.

**Right Arrow**—On a highlighted match on the left side of the dialog, removes the match and moves the source bone to the right side of the dialog.

**Match by Name**—Matches the source and target bones by name. You can use this option only if you have removed prefixes or suffixes to make the displayed source and target bone names match exactly.

**Threshold**—Sets the unit distance that the utility will search for vertex or face matches. Default=1.0.

**Interpolation**—Sets the method by which pasting will take place. Use the Match by Vertex option only if the meshes are identical. Otherwise, use Match by Face. Default=Match by Vertex.
reactor is a toolset that allows animators and artists to control and simulate complex physical scenes in 3ds Max. reactor supports integrated rigid and soft body dynamics, cloth simulation, and fluid simulation. It can simulate constraints and joints for articulated bodies. It can also simulate physical behaviors such as wind and motors. You can use all of these features to create rich dynamic environments.

Once you have created an object in 3ds Max, you can assign physical properties such as mass, friction, and elasticity to it with reactor. Objects can be fixed, free, attached to springs, or attached together using a variety of constraints. By assigning physical characteristics to objects like this, you can model real-world scenarios and then simulate them to produce physically accurate, keyframed animations.

After you set up your reactor scene, you can preview it quickly using the real-time simulation display window. This allows you to test and play with a scene interactively. You can alter positions of all physical objects in the scene, dramatically reducing the design time. You can then transfer the scene back into 3ds Max with a single mouse click while retaining all the properties needed for the animation.

reactor frees you from having to hand-animate time-consuming secondary effects, like exploding buildings or draping curtains. reactor also supports all standard 3ds Max functionality such as keyframes and skinning, so you can use both conventional and physical animation in the same scene. Convenient utilities, such as automatic keyframe reduction, let you tweak and alter the physically generated parts of an animation after it has been created.

The remainder of this chapter describes each of reactor’s features in detail. Also, the included tutorials step you through creating some typical reactor scenes. Together, we hope these will help you to get the most from reactor.

If you would like to find out more about dynamics simulation, see Introducing Dynamics Simulation (page 2–707).

Getting Started
This section shows you where to find the various reactor options in 3ds Max, as well as introducing you to reactor’s helper icons. You’ll see how to use each of the options in the relevant section of this guide.
Command Panel
You can use the reactor options on the Create panel to create various reactor elements. To find most reactor objects, go to the Helpers sub-panel, and then, from the drop-down list, choose reactor.

Once you’ve created a reactor object, selecting the object and opening the Modify panel allows you to configure its properties.

You can also find a space warp, used for water (page 2–801), in Space Warps > reactor.
There are also three reactor modifiers, used to simulate *deformable bodies* (page 2–777):

You'll find most of the remaining reactor functions on the Utilities panel. This provides access to functionality such as previewing the simulation, changing world and display parameters, and analyzing the convexity of objects. It also lets you see and edit the rigid body properties associated with objects in the scene.
Note: The reactor menus and toolbar provide shortcuts for many of the reactor functions provided in the command panel.

The reactor Toolbar

The reactor toolbar is a handy way to access much of reactor’s functionality. It has buttons that let you quickly create constraints and other helpers, display physical properties, generate animations, and run the real-time preview.

To display the reactor toolbar:

1. Right-click an empty area of the main toolbar to display a list of available toolbars.
2. Click reactor.

The reactor Menu

The main reactor menu is another way to access reactor functionality.
Introducing Dynamics Simulation

The reactor Quad Menu

A further quick way to access reactor options is the reactor quad menu. To open this menu, press \textbf{Shift+Alt} and right-click in the active viewport.

Helper Icons

Many reactor elements, such as constraints and the Rigid Body Collection, have their own special helper icon that appears in the viewport when you add them to the scene. For instance, the following illustration shows the Hinge constraint icon:

Although the helper icon doesn't appear in your rendered scene, the icon's appearance (and in some cases, its position and orientation) will help you to set up your reactor scene correctly.

When selected, reactor icons are white and are also larger than when not selected. When not selected, the icon for a valid element is blue, and for an invalid element is red. What constitutes validity depends on the particular reactor element. For instance, a hinge (page 2–747) is valid if it has the correct number of objects attached to it; a Rigid Body Collection (page 2–723) is valid if it's not empty. Invalid elements are excluded from the simulation, and reported as errors.

Certain icons provide additional information about how the element behaves in the simulation. For example, the display for a valid hinge indicates the hinge position, and, when selected, the hinge axis and any limits you have specified for the movement of the hinged bodies.

Introducing Dynamics Simulation

This section gives a broad overview of physical simulation, and introduces some concepts you might find useful when working with reactor.

Physical Simulation

\textit{Havok}'s physics technology, used in reactor, relies on a process known as \textit{physical simulation} in order to provide a dynamic environment for the objects in a scene. So what exactly does \textit{physical simulation} mean?

It is a process that automatically determines the motion of objects according to their physical properties. It achieves this by encapsulating some physical laws, like Newton’s laws of motion, within a robust, efficient engine, which calculates the position of each object as time passes. In much the same way that a motion picture is composed of many individual images or frames, physical simulation splits time into small discrete steps and predicts the motion of each object during each step. The cumulative effect of all these steps is fluid, continuous, believable motion.
Unlike traditional keyframe-based animation, where the animator needs to specify a set of keyframed configurations, physical simulation determines how objects move based on their properties. This takes the burden from the animator, who now doesn’t need to manually animate every piece in an explosion, every bone in a character stunt animation, or every vertex in a piece of cloth.

In a physical simulation, physical properties such as mass and elasticity are assigned to all objects in the scene. This is then complemented with a set of external forces like gravity or wind and/or constraints, like a spring force or a ball-socket configuration. From all this information, the physics engine calculates a continuous set of states that can then be displayed in real-time, if the calculations are fast enough, or converted into keyframes to be played back later.

**What Does A Physics Engine Do?**

A physics engine like Havok has three basic tasks to perform:

1. **Collision Detection**
   Track the movement of all the objects in the scene and detect when any of them have collided.

2. **Update System**
   Determine an appropriate response for objects that have collided by resolving the collision according to the object properties and for all other (non-colliding) objects update them according to the forces acting on them.

3. **Interface with Application**
   Once reactor determines the new positions and state of all objects, it can display the objects in a 3D window or store their states in the form of keyframes.

**Note:** A physics engine knows nothing about how the objects it is simulating are displayed. It simulates the motion and interaction of these objects based on a physical (not graphical) description of the objects, and this information can be used to generate a display that “tracks” the simulation.

Given that we are talking about simulating a continuously evolving state (in other words, objects are moving and colliding and reacting all the time in general), we need to map this to a series of snapshots in order to generate an animation. In a computer game, for example, we typically want to display the world 60 times per second, because this is how frequently many graphics systems can redraw the screen. When creating an animation, we may want to store the state (that is, create a keyframe) for every frame. At 60 FPS, for example, this would also create 60 keyframes every second.

This really means that the physics engine must be capable of evolving the world by 1/60th of a second knowing the state of all the objects at the start of this time interval and knowing the external forces acting on these objects. As an example we'll look at the simple case of a cannon ball and we'll assume we're interested in animation at 60Hz (Hz = cycles or frames per second).

**Simulating a Cannon Ball**

Let’s forget about collisions for now, and consider only the simulation of a cannon ball immediately after it has been fired from the cannon. We know the ball’s position (and orientation, but we’ll ignore this for now), speed, acceleration, and weight, and we assume we know the state of the environment (air resistance, wind force, gravity). Armed with this knowledge we can start to make predictions using a physics engine.
This figure illustrates what we would like to achieve. Over a period of time the cannon ball’s rate of ascent should slow due to gravity, and it should eventually fall to the ground having traveled through a classic parabolic arc (assuming no air resistance).

At a given point in time we can examine the state of the ball (its speed $v$ and acceleration $a$) and knowing the external forces acting on it we can make a guess as to its change in position after a period of time has elapsed (call this period $h$ seconds). This guess is a combination of a number of factors:

- We assume that Newton’s laws of motion govern the motion of the ball
- We assume that in the time period $h$ all the external forces acting on the ball are constant, so air resistance and wind and gravity do not change during this time.
- We assume that the math we use to calculate the new position is accurate

In general, the first assumption is usually valid, except at relativistic or quantum scales, which we can assume should be handled by other systems. The remaining two, however, cause problems and are closely linked to the time period $h$ over which we’re performing the calculations. We’ll now examine the effect of the size of this time period on the accuracy of the simulation.

**Time Steps**

In general, the forces acting on an object are rarely truly constant; gravity is close to being constant, but most other forces like wind and air resistance are not. So, taking the cannon ball example, imagine a windy layer in the atmosphere that the cannon ball passes through, as shown in the next figure.

In the simulation on the left we assume we’re taking steps of one second; this is actually a relatively large interval for a physics simulation, but is used here to illustrate the point. We know all the forces acting on the ball at time $t_1$ so we use some math to predict the new position and velocity at time $t_2$, after one second has elapsed. During this period, we assume that the wind force acting on the ball is constant. In this example, we’ll calculate the new position above the region of high wind, so we effectively have missed the windy bit by taking too great a jump. In the second example on the right, we’re using time steps of $\frac{1}{2}$ second. In this case, after determining the new position at time $t_2$ we find the ball in the middle of the windy region. This region causes a large wind force to act on the ball which is taken into account during the next time step. At that point we reevaluate the math and determine a new position for the ball at time $t_3$. This is different from the position determined in the simulation on the left, even though the same amount of time has been simulated in each case. In other words, the wind has blown the ball to the left a bit and has reduced the velocity of the ball.

In general, the smaller the time step taken, the more accurate the result at the end of the time step. Thus, to step forward in time by a large time step
t it is better to split this into n steps of a smaller time interval t/n.

This is also true of the math. As the simulation becomes more complex, the math required to calculate the new positions and velocities of objects in a simulation also becomes more complex, and as a result the guesses produced by the math give progressively less-accurate results.

So the principle is to take small time steps, evaluate all the forces acting on the objects, determine the new positions and velocities (and other parameters) of the objects at the end of the time steps, and then start over. We end up with a series of snapshots of the state of the system as it evolves, as shown in the following illustration.

Substeps

In the previous section, we said that the physics engine passes on the necessary information to update the display after it determines the new positions for all its objects. However, what if you don’t want to update the display in each simulation time step?

Let’s say we absolutely need to update the application once every 1/60th of a second, either because we’re playing a real-time game that refreshes the screen at 60Hz. or we’re creating a keyframe every frame for a 60FPS movie. This effectively means that we want to step the physics engine at intervals of 1/60th of a second. In many cases this does not present a problem, but if, hypothetically, the accuracy of the simulation was not sufficient (remember: smaller time steps mean better accuracy), then we’d like to decrease the time step even further, say to 1/120th of a second. But this would mean we generate twice the number of images/keyframes we are interested in, which is wasteful. To get around this, the Havok engine allows you to specify the number of substeps to take per key.

The Substeps/Key parameter specifies the number of steps the physics engine takes before updating the application. This gives control over the granularity of the physics simulation independent of the display update or keyframe-creation frequency. So with Substeps/Key=1, reactor uses a single simulation step for each update to the 3D display. With Substeps/Key=2, reactor takes two physics steps each time before updating the application, and so on.

In this figure, we have specified that the physics simulation should step at intervals of 1/240th of a second, but that we create a keyframe only once every 1/60th of a second. The red spots indicate a keyframe and simulation step, the yellow spots
are simulation steps only. This was achieved by instructing the physics engine to employ four substeps per key. Thus, for each four simulation steps we create only keyframe. By setting the number of substeps we can control the accuracy of the physical simulation independent of the number of keyframes created.

**Rigid Bodies and Deformable Bodies**

**Rigid Bodies**

Havok simulates most objects in a simulation as *rigid bodies*. A rigid body is an object whose geometry doesn't change over the course of the simulation. You can simulate any real-world object that doesn't noticeably change its shape, from a pen to a boulder hurtling down a mountainside, as a rigid body. Simulating objects in this way facilitates rapid physical simulation in real time; the physics engine can make certain assumptions when detecting collisions based on the fact that the objects' shapes don't vary from simulation step to simulation step.

Both the Havok 1 and Havok 3 engines can simulate rigid bodies, but Havok 3 simulations are faster and more accurate.

**Deformable Bodies**

To simulate cloth, rope, or other material whose shape changes over time, you need to use a different type of body: a deformable body. With deformable objects, collision detection becomes much more difficult, given that the object can change shape dramatically between time steps and can also attempt to collide with itself. For this reason, deformable bodies are more expensive to simulate.

Note: Only the Havok 1 engine can simulate with deformable bodies.

**Scale**

Our scientific knowledge of physics is extensive. What we are concerned with here would more accurately be described as a mechanical simulation of the interactions of objects at real-world scales. We are dealing with Newtonian mechanics; that is, the well-understood laws of motion, popularized by Sir Isaac Newton, that describe the behavior of objects under the influences of other objects and external forces. Since then we've discovered that these laws break down at very small (i.e. subatomic) and very large (i.e. planetary) scales.

New physics systems have been devised to work with these scales (for example, relativistic and quantum), but these are beyond the scope of the reactor physics engine. The Havok physics simulation technology works at the scale of objects we interact with on a daily basis, such as chairs, cars, buildings, and footballs. By default, the engine works in units of meters and kilograms.

It's important to keep in mind the scale in which you're working. For example, a common mistake people make is to start by creating a cube 100 meters on a side, and then they wonder why it takes so long to fall. A box of this size when viewed at a distance sufficient to be able to see the entire box (say 1km away) will appear to fall at the same speed as an aircraft hangar dropped from a height and viewed from a kilometer away: slowly.

**Changing Scale**

The Havok physics engine does not care what units of measurement you use when specifying the size of objects or the strength of gravity; it cares only about the numbers. So you could, for instance, work in inches. However, for realistic (or at least predictable) results, it’s important to be consistent. So, for instance, if you’re working in meters, make sure gravity is set to an appropriate value in meters. To produce Earth-like gravity, use
9.8 m/s². Otherwise objects might appear to fall faster or slower than you expect.

Note: Due to CPU floating-point precision, a physics engine is most accurate when dealing with numbers as close in magnitude to 1 as possible. In other words, values like 10,000,000 work poorly, as do values like 0.0000001. Therefore, for real-world scenes, when creating objects of 1*1*1 size it is most useful to be working in meters or feet, rather than centimeters/inches or kilometers/miles, in that you most often simulate objects larger than sugar cubes and smaller than football fields. It is for this reason that the default values in many physics engines are usually specified in meters.

Special Features in reactor

A number of reactor features enhance speed and usability. The software lets you create new and better animations that were virtually impossible without reactor, and you can set up those animations in an efficient, intuitive way. Here we present some of the main features in reactor.

Two Simulation Engines

From the reactor utility interface, you can choose to run your simulation with either of two engines: Havok 1 or Havok 3.

If your reaction involves cloth, rope, or soft bodies, you'll need to stick with Havok 1, the version included with previous releases of 3ds Max. However, if you’re using rigid bodies only, you can take advantage of the enhanced accuracy available in Havok 3. For more information, see The reactor Utility (page 2–805) and Havok 1 World/Havok 3 World Rollout (page 2–808).

Integrated User Interface

The reactor interface is fully integrated in 3ds Max. You can access functionality in reactor through menus, quad menus and toolbars. All 2D and 3D icons follow a consistent look and feel. The reactor utility (page 2–805) parameters are arranged for easy access.

You can find more details in:
- reactor (page 2–703)
- The reactor Utility (page 2–805)

Vertex Selection Inside reactor Modifiers

The reactor modifiers for deformable bodies (page 2–777): Cloth, Soft, and Rope, let you select vertices and apply constraints (fix points, keyframe points, attach to rigid body, attach to deforming mesh) to those vertices without leaving the modifier or having to apply extra modifiers. You can create and manipulate deformable constraints (page 2–795) inside the modifier.
**Cooperative Constraints**

reactor includes a number of cooperative constraints (page 2–735) that facilitate the simulation of articulated bodies and machinery.

The Rag Doll constraint (page 2–737) allows the simulation of constrained bodies with relative rotation and twist angles limits similar to those found in human and animal joints.

The Hinge constraint (page 2–747) allows the simulation of hinges (limited or not) and hinge-like joints where movement is limited around a specified axis, like elbows and knees.

The Prismatic constraint (page 2–754) allows the simulation of translation-only joints (limited or not) like those found in robots and machinery.

The Car-Wheel constraint (page 2–757) is particularly suited to the simulation of wheels attached to a chassis. The wheels rotate (and can be powered) about a given axis. Limited linear motion relative to the chassis is allowed along a user-defined suspension axis.

Using Point-Point constraint (page 2–750) with the Limited option lets you limit the relative rotation of the attached objects by a given degree around each axis.

Using Point-Point (page 2–750) with the Stiff Spring option constrains both objects as though attached by a fixed-length bar (a very stiff spring).

**Fracture Object**

The Fracture (page 2–770) object in reactor offers excellent usability and behavior. Objects inside Fracture are standard Rigid Bodies and, as such, you can add them to constraints, assigned initial velocities, etc. You can tell pieces to break at a specific time.

**Constraint Manipulation and Constraint Spaces**

Constraints (page 2–724) in general restrict the relative movement between two bodies (parent and child) or between a body (child) and the world, and use consistent, intuitive nomenclature and setup methods. Springs, linear dashpots and angular dashpots are referred as Simple Constraints (page 2–727), while the other constraints (those that are grouped with a Constraints Solver (page 2–736)) are referred to as Cooperative Constraints (page 2–735).
In reactor, you define the effect of constraints by specifying and manipulating two constraint spaces (page 2–725). Limits, such as minimum and maximum rotation angles, are defined and displayed around those spaces, which you can modify using sub-object manipulation. reactor provides tools for automatically aligning and manipulating those spaces.

Storage and Access of Collision Information

reactor can store information of all rigid body collisions occurred during the simulation. The information includes the objects involved, the point of collision, and the relative velocity during collision, and can be used by animators to generate particles or other effects, trigger sounds, etc. You can access the information via MAXScript and save it to a text file.

For more information, see Storing and Accessing Collisions (page 2–774).

Support for Global Collisions

In reactor, you can enable or disable collisions globally instead of inside the Rigid Body Collection (page 2–723). The software stores disabled collisions inside the reactor Utility (page 2–805). You can disable collisions not only for rigid bodies, but also for cloth, soft and rope. And you can access disabled collisions through MAXScript.

Animatable Wind

You can animate most parameters in the reactor Wind (page 2–803) object, including wind speed and direction. Range and Falloff parameters let you set up the range of action for the wind.

Cloth/Soft/Rope Attachments to Deforming Meshes (Skin)

The Attach to DefMesh (page 2–799) deformable constraint allows vertices in cloth, soft bodies, and rope to follow a non-rigid mesh such as skin.
Soft Selection for Cloth/Soft/Rope

The deformable (page 2–777) (cloth/soft/rope) modifiers in reactor can now use the soft selection flowing to that modifier and blend the current vertex animation with the reactor animation, facilitating the transition between skin-driven and reactor-driven animation.

Floating Rigid Body Property Editor

In reactor you can change the rigid body properties (page 2–716), like mass, elasticity or friction without having to use the reactor Utility (page 2–805). You can open a floating MAXScript window to modify rigid body properties from the reactor menus, quad menus, and toolbars at any time.

MAXScript Access

Virtually all parameters and functionality in reactor are accessible through MAXScript.

Animation Features

reactor can automatically create list controllers (or character studio layers) to store the animation of rigid bodies. For more information, see Preview & Animation Rollout (page 2–806).

Also, the ragdoll script (page 2–818) is aware of being applied to character studio bipeds, and, in such cases, sets up the constraints so that, when you create an animation, the biped is physically animated.

reactor Helpers

Create panel > Helpers > reactor
reactor menu > Create Object

This topic simply provides links to the various helper objects that are part of the reactor system.
Rigid Bodies

The rigid body is the basic building block of reactor simulations. You can use a rigid body in reactor to simulate any real-world object that doesn’t change its shape, from a pen to a boulder hurling down a mountainside.

You can create a rigid body using any geometry in a 3ds Max scene. reactor then lets you assign the properties the object should have in the simulation, such as mass, friction, and whether the body can collide with other rigid bodies. You can also restrict the possible movement of your rigid bodies in the simulation using constraints such as hinges and springs.

This chapter shows you how to create and work with rigid bodies in reactor. It includes the following topics:

- Rigid Body Basics (page 2–717)
- Rigid Body Collection (page 2–723)
- Constraints (page 2–724)
To find out how to simulate objects that change their shape over time, see Deformable Bodies (page 2–777).

Rigid Body Basics

You can make a rigid body from any geometry in your scene. A rigid body can be a single object, or it can comprise several objects grouped together, known as a compound rigid body (page 2–722). If you designate an object whose geometry changes over time as a rigid body, the simulation uses its geometry at the start frame.

reactor lets you assign the physical properties that each body will have in the simulation, such as mass, friction, and whether the body can collide with other rigid bodies. You can specify a proxy geometry for a rigid body, which allows reactor to treat the rigid body as an easier-to-simulate shape for the purpose of the simulation. You can also specify how your rigid body should be displayed when previewing the simulation.

An object is simulated as a rigid body after you have added it to a Rigid Body Collection (page 2–723); you can edit its rigid body properties before or after you do this.

This section tells you how to:

Edit rigid body properties (page 2–717), including

- physical properties (page 2–718)
- simulation geometry (page 2–719)
- display properties (page 2–722)
Interface

Physical Properties

- Mass—A rigid body’s mass governs how the object interacts with other objects. When its mass is set to 0.0 (the default value), the object remains fixed in space during the simulation, although other objects will be able to collide with it. For example, you could use a fixed rigid body to create a slope for other objects to roll down. Other values allow the object to move during the simulation, depending on other circumstances. A valid value for Mass is greater than or equal to 0.0.

- Friction—The coefficient of friction for the object’s surface. This affects how smoothly the rigid body moves relative to surfaces it’s in contact with. The friction values for both objects combine to produce a coefficient for the interaction. To achieve realistic results, use values between 0.0 and 1.0. However, values up to 5.0 are accepted.

- Elasticity—This value governs the effect collisions have on the velocities of the rigid body; in other words, how “bouncy” the object is. Like Friction, this is a pair-wise coefficient: When two objects collide, their elasticity values combine to produce a coefficient for the interaction. To achieve realistic results, use values between 0.0 and 1.0. However, values up to 5.0 are accepted.

- Inactive—When on, the rigid body starts the simulation in an inactive state. This means it requires interaction with another object or system, or the mouse, before it becomes active in the simulation. For example, if you place an object in midair, give it a mass and set it to Inactive, when the simulation starts it sits in midair until something interacts with it. Inactive objects require less computation during simulation.

- Disable All Collisions—When on, the object doesn’t collide with other objects in the scene; it simply passes through them.

- Unyielding—When on, the rigid body takes its motion from the animation it already has in 3ds Max, rather than the physical simulation. Other objects in the simulation can collide with it and react to its motion, but its motion is governed solely by the current animation in 3ds Max, and reactor will not create keyframes for it.

- Phantom—A phantom object has no physical presence in the simulation. Like an object with Disable All Collisions on, it simply passes through other objects. Unlike an object with disabled collisions, however, a phantom maintains collision information about any objects that it passes through during the simulation. You can then use this collision information, for instance, to trigger sounds or other effects. You can find out how to access collision data in the Storing and Accessing Collisions (page 2–774).

- Shell—The radius of an extra “shell” around convex shapes, which reactor uses as the shape’s surface for collision-detection purposes. The simulation tries to ensure that the distance between this shell and other objects is always more than zero; in other words, that the distance between the original
convex shape and other objects is always more than the combined radii of the objects. Default=0.05.

**Important**: Applies to Havok 3 only.

Adding a shell to an object can improve performance. The core convex-convex collision-detection algorithm is fast when objects are not interpenetrating, and slower when they are. Adding a shell makes it less likely that the shapes themselves will interpenetrate, thus reducing the likelihood of using the slower algorithm. Using a shell is thus faster in situations that involve the risk of shapes interpenetrating; for instance, when an object is settling or sliding on a surface, when there is a stack of objects, or when many objects are jostling together.

**Penet.**—(Penetration) The amount of penetration reactor permits.

To avoid trying to solve insoluble physical problems, the Havok 3 engine allows penetration between objects even if continuous physics is enabled. Default=0.05.

**Important**: Applies to Havok 3 only.

**Quality**—Lets you set individual settings for each object based on the desired level of interaction. Default=Moving.

**Important**: Applies to Havok 3 only.

The available Quality settings are:

- **Debris**—Low-importance objects used for adding visual quality.
- **Moving**—Regular objects that populate the world, such as furniture, etc.
- **Critical**—Essential objects that are never allowed to interpenetrate.
- **Bullet**—Fast-moving projectiles.

**Simulation Geometry**

Lets you specify the physical representation of your object that will be used in the Havok simulation.

**Proxies**

reactor supports substituting one object for another in two different ways: geometry proxies and display proxies.

Geometry proxies allow you to specify a different body’s geometry as the simulation geometry for an object. For example, you can have a complex object displayed on-screen, but replaced for simulation purposes by a box, which is much easier and faster for reactor to simulate. The box governs the movement of the object, and dictates how it collides, its position, and orientation. However, on-screen you can see the complex object in full detail. Geometry proxies are applied per object.

Display proxies replace a rigid body’s display body with that of another object. Therefore, they affect display only during the real-time preview (page 2–815) and do not affect animation. They are applied per rigid body, rather than per object. This means that you can create a compound rigid body of several objects and simulate these, but display an alternative mesh for the body during the preview. You can find out how to specify a display proxy in the **Display (page 2–722)** section.

**Convex and Concave Objects**

A rigid body primitive is defined as convex if, given any two points inside the object, you can always go in a straight line from one to the other without leaving the object. Convex objects include spheres, cylinders, and boxes. For example, a sphere is convex but a golf ball is concave because of the concavities (dimples) in its surface. Also, by definition, non-closed meshes (planes, hollow hemispheres) are always concave.
Convex objects are faster to simulate than concave objects. Because of this, you should aim to use convex objects as often as possible for simulation. Treating concave objects as convex for simulation purposes allows you to take advantage of their faster processing time. This is the default setting for an object’s simulation geometry (Mesh Convex Hull). If you are unsure whether an object is convex or concave, you can perform a convexity test on it. With the object selected, open the reactor - Utilities menu and select Convexity Test.

You can specify one of the following simulation geometry options to define how your object will be represented in the physical simulation. To view the simulation geometry for your objects in the preview, as in the following examples, select Sim Edges from the Display menu in the Preview Window.

**Bounding Box**—The object is simulated as a box whose extents are determined by the object’s dimensions.

**Bounding Sphere**—The object is simulated as an implicit sphere. The sphere is centered on the object’s pivot point and then minimally encloses the object’s geometry.

**Mesh Convex Hull**—This is the default option. The object’s geometry is passed through an algorithm that creates a convex geometry using the geometry’s vertices, completely enclosing the geometry’s vertices. To visualize this, imagine shrink-wrapping a teapot: The teapot is concave but its shrink-wrap forms a convex hull.
Proxy Convex Hull—The convex hull of another object is used as the physical representation of the object in the simulation. For instance, you could use the convex hull of a low-poly teapot to simulate a high-poly teapot. The proxy object’s pivot point is aligned with that of the rigid body.

Concave Mesh—The actual mesh of the object is used for simulation. Although the convex hull of an object and the object’s actual mesh may be exactly the same shape, using the convex hull simulates much more quickly, as reactor can make certain assumptions for convex objects. If you try to use Concave Mesh for a convex object you will get a warning. Not heeding such warnings could dramatically reduce the speed of your simulation. In some cases, though, you might want to ignore that warning. If, for example, you want to place objects inside a convex object, and make them collide with the internal faces of that object, you should simulate it as concave instead of convex.

Proxy Concave Mesh—Another object’s concave mesh is used as the physical representation of the object. For example, you can use a low-poly teapot to animate a highly tessellated teapot. The proxy object’s pivot point is aligned with that of the rigid body.

Note: If you are using a standard 3ds Max plane as a rigid body (as opposed to the special reactor Plane (page 2-764) object), you must set its simulation geometry to Concave Mesh.

Not Shared—This option is active only when multiple objects with different Simulation Geometry settings are selected, and cannot be chosen by the user.
Chapter 13: reactor

Display

Use Display Proxy—When on and you specify a proxy object by clicking the Proxy button, reactor displays the specified proxy in the Preview Window in place of the object.

Compound Rigid Bodies

Rigid bodies can be made of one or more objects, or primitives. For instance, if you assign physical properties to an object in a scene and add it to a Rigid Body Collection, we say that the rigid body has one primitive. However, reactor can also simulate a rigid body made up of more than one primitive. To do this, you need to group objects together using the 3ds Max Group menu. You can then add the group to the collection, and the objects in the group then become the primitives that make up the rigid body.

Creating such compound rigid bodies can be useful, as it is much faster to simulate a rigid body made up of convex pieces than to simulate a more complex concave shape. In addition, the primitives that make up a compound rigid body can have different masses, so you can create rigid bodies that have nonuniform mass distribution. For example, you can create a hand axe where the head is heavier than the handle, so that if you toss the axe it spins around its head.

You can do this because the Mass property on the Rigid Body Properties dialog is assigned to a specific primitive rather than an entire rigid body, unlike most of the other properties in this dialog. For single-primitive rigid bodies, this distinction is unimportant. However, in the case of a compound rigid body, the group parent is the rigid body and cannot have a Mass value assigned: Mass can be assigned only to its children, the primitives.

Simulation geometry is also defined at a primitive level, so you can combine concave and convex hull geometries in a single rigid body.

Procedures

To create a compound rigid body:

1. Arrange the objects to use to make up your compound rigid body.
2. Select all of the objects.
3. From the Group menu, choose Group. Your objects are now all child objects of a new group parent. You can add this parent object to a Rigid Body Collection.

To edit compound rigid body properties:

1. With the compound rigid body selected, choose Group > Open.
2. To edit the compound rigid body’s properties, select the parent (dummy) and go to the properties rollout of the utility or open the Rigid Body Properties dialog. You cannot edit the Mass or Simulation Geometry values for a group parent because they are primitive properties.
   
   Tip: It’s easier to select a group parent using the Select Objects dialog (page 1–78) with Display Subtree enabled: The group parent is displayed above its members.
3. To edit one of the rigid body’s primitive’s properties, select the appropriate child and go to the Properties rollout of the utility or
open the Rigid Body Properties dialog. You can give this object a Mass value and, if you wish, change its Simulation Geometry setting. Specifying any other rigid body properties for a child object has no effect unless you remove the object from the group.

Rigid Body Collection

Create panel > Helpers > reactor > RBCollection
Menu bar > reactor > Create Object > Rigid Body Collection
reactor toolbar > create Rigid Body Collection button

The Rigid Body Collection is a reactor helper object that acts as a container for rigid bodies. Once you have added a Rigid Body Collection to your scene, you can add any valid rigid bodies in the scene to the collection. You can find out more about rigid bodies in the Rigid Body Basics (page 2–717) section.

When you run the simulation, reactor examines the Rigid Body Collections in the scene and, provided the collections are not disabled, adds the rigid bodies they contain to the simulation.

At a lower level, a collection also allows you to choose the mathematical method to be used for solving the rigid body behaviors for its member bodies.

Procedures

To create and use a Rigid Body Collection:

1. Choose any of the above commands, and then click in any viewport to add the Rigid Body Collection.
   Note: The icon’s position has no effect on the collection’s behavior.

2. Add objects to the collection using either (or both) of these methods:
   - On the RB Collection Properties rollout, click the Pick button, and then in the viewport click an object to add.
   - On the RB Collection Properties rollout, click the Add button, and then use the Select Rigid Bodies dialog to specify one or more objects to add.

To create a collection and add bodies in a single step:

1. Create and select the object(s) to add to the collection.

2. Create the collection using the reactor toolbar, reactor menu, or quad menu. reactor instantly places the collection in the scene and adds the selected objects to the collection.

Interface

RB Collection Properties rollout

Highlight—Cause the objects in the Rigid Bodies list to display momentarily in the viewports as if selected.
Rigid Bodies—Lists the names of the objects in the Rigid Body Collection.

Pick—Lets you add an object to the Rigid Body Collection. Click this button, then in the viewport move the cursor over the object you would like to add to the collection. If the object can be used as a rigid body the cursor will change from an arrow to a cross and you can select the object to add it to the collection.

Add—Lets you add one or more objects from the scene to the collection. Click the button to open the Select Rigid Bodies dialog. Make a selection in the provided list, and then click the Select button to add the objects to the collection.

Delete—Lets you remove objects from the collection. In the rigid bodies list, select the bodies you would like to remove from the collection and click this button.

Disabled—When on, the collection and the bodies it contains are not added to the simulation.

Advanced rollout

- Advanced

  - ODE Solver
  - Euler
  - Runge-Kutta

  Reset Default Values

ODE Solver—Lets you choose the method by which reactor simulates the collection:

- **Euler**—The collection calculates the behavior for its rigid bodies using an Euler ODE (Ordinary Differential Equation) solver. Euler is a fast method that provides good results in most cases.

- **Runge-Kutta**—This method is more accurate in some cases but requires more computation. Use Runge-Kutta if you have many object connected using simple constraints (page 2–727) like springs or dashpots, because those kind of systems can easily become unstable.

Reset Default Values—Sets values for the collection to their defaults. In this instance, it sets the ODE Solver back to its default value.

Constraints

With reactor, you can easily create a simple physical simulation by simply assigning rigid body properties to objects and adding them to a Rigid Body Collection. When you run the simulation, objects can fall from the sky, slide across each other, bounce off each other, and so on. However, let's say you want to simulate a real-world scene such as a person pushing open a door. How, for instance, do you make sure that the door rigid body doesn’t just fall onto the ground, or that it swings out in the proper direction when pushed?

To accomplish this you use *constraints*. These let you restrict the possible movement of objects in the physical simulation. Depending on the type of constraint you use, you can hinge objects together, attach them together with springs that will snap back if the objects are pulled apart, or even simulate the movement of a human body joint. You can constrain objects to each other or to points in space.

This section shows you how to work with constraints in reactor. It includes the following sections:

*Constraint Concepts (page 2–725)*

*Simple Constraints (page 2–727)*, which includes the following topics:

* Spring (page 2–727)*

* Linear Dashpot (page 2–730)*
Constraint Concepts

This section introduces some common concepts that you’ll need to understand to work with any of the reactor constraint types.

Constraints, Simple Constraints and Cooperative Constraints

You use constraints in reactor to specify limitations in the movements of objects. Without constraints, the movement of objects could be limited only by collisions and deformations. This is the case in the real world: For example, a door’s movement is limited by a set of pieces that form a hinge; the collisions between those objects limit the movement of the door. The motion of two objects attached by a spring is limited by the deformation of the spring. A train can move only along the path defined by a rail due to the collisions of its wheels with the rail. In many cases, though, it is preferable to specify explicitly the effect of those objects (hinge, spring, rail) rather than model them and simulate them. This is what constraints are for.

A constraint lets you limit the way an object can move. Once you specify a constraint, reactor tries to enforce it during the simulation. For example, you can use a Hinge (page 2–747) constraint to simulate the effect of an actual hinge on an object:

- No translation is allowed, and rotation is allowed around only one axis. Similarly, you can use a Spring (page 2–727) constraint to simulate the effect of a spring (translation is limited to a certain length); or a Point-Path (page 2–762) constraint to simulate the effect of a rail (translation and orientation are limited to follow a path).

Sometimes you will have a system of many objects constrained together. For example, if you want to simulate a character falling down the stairs, you might constrain the different bones of the character using many constraints (like Rag Doll (page 2–737) or Hinge (page 2–747)). Because all the bodies are connected, maintaining one constraint may affect the other constraints, so it is better if they are simulated together, so they are aware of each other. Thus, some constraints require you group them so they can be solved as a system. Those constraints are called Cooperative Constraints (page 2–735) and are usually more stable, although they can be slightly slower to simulate. The other constraints, Simple Constrains (page 2–727), cannot be grouped and therefore are more prone to instability in complex scenes, but are faster to simulate.

Constraint Spaces

In rigid body dynamics, each body has six degrees of freedom to move:

- three translational degrees of freedom
- three rotational degrees of freedom

Each type of reactor constraint can remove or limit one or more of these degrees of freedom for its constrained bodies.

Depending on the number and type of these limitations, we get different types of constraint, from the simple Point-Point (page 2–750) constraint to the much more complicated Rag Doll (page 2–737) constraint. For example, with a Point-Point constraint, the constrained objects...
are completely free to rotate around the constraint pivot point, but have no linear freedom relative to each other in any direction; they are attached together at the point. However, with a Rag Doll constraint, the objects not only have no linear freedom, but their possible relative orientation is also restricted.

In each constraint, these angular and linear limits are defined in terms of the constraint's coordinate system or constraint space. Because a constraint restricts the movement of its objects relative to each other, a constraint also needs to maintain a mapping from each object's local space to the constraint space. reactor lets you manipulate the constraint space in each object's local space separately, as you'll see in the Working With Constraint Spaces (page 2–726) section.

Parents and Children

Each reactor constraint can have two objects: a parent object and a child object. Although two-bodied constraints actually restrict the possible movement of both bodies, it is often simpler to specify how one object is allowed to move relative to the other one, particularly when you are using limits. With reactor, you specify how the child object can move relative to the parent.

For some constraints, it makes no difference which object is the parent and which is the child. For instance, if you use a Point-Point constraint to attach two objects together at a common point, it works in exactly the same way regardless of how you specify the attached objects.

However, with the more complex Rag Doll constraint, which you typically use to model body joints, it's important to specify which object is the parent. This is because this constraint lets you specify a number of limits on how the child can move relative to the parent object. For example, when you move your torso, your arm always moves with it. So when modeling a shoulder joint, you would specify that the torso object is the parent, making the arm object the child. You can then specify limits on the arm's movement relative to the torso.

When you constrain an object to a point in world space rather than another object, the constrained object is the child object and there is no parent object.

Working With Constraint Spaces

For most constraints, by default the constraint space is aligned with the child body. This means that the constraint pivot/attachment point is positioned at the child object’s pivot point, and the constraint space takes its orientation from the child body’s local space. The exceptions to this are the constraints with two attachment points, Springs and Stiff Springs, and the Point-Path constraint, each of which has its own default alignment.

You can move the constraint space relative to each of the bodies by going to the constraint's Parent Space or Child Space sub-object level in the modifier stack, and then using the Move and/or Rotate tools. The space will then maintain its position and/or orientation relative to the corresponding object during the simulation.

reactor also provides some quick shortcuts for aligning constraint spaces, available with each constraint. These are:

- **Align Spaces To Child Body**—This is the default alignment for all constraints except Spring, the Stiff Spring variant of Point-Point, and Point-Path.

- **Align Spaces To Parent Body**—The constraint space is aligned with the parent body: The pivot point is positioned at the parent body's pivot point, and the constraint space takes its orientation from the parent object’s local space.

- **Align Spaces To Child Space**—Aligns the parent and child constraint spaces with the child’s
constraint space. So, for instance, if you move the constraint space relative to the child, you can use this option to move the parent’s constraint space into alignment with it.

- **Align Spaces To Parent Space**—Aligns the parent and child constraint spaces with the parent’s constraint space. So, for instance, if you move the constraint space relative to the parent, you can use this option to move the child’s constraint space into alignment with it.

Certain constraints have additional alignment options:

- **Align Spaces To Each Body**—(Spring and Point-Point > Stiff Spring only) This option aligns each local constraint space (and hence the spring attachment point) with the relevant body, so each body’s attachment point is at its pivot. It also sets the spring length to the current distance between the nodes. This is the default alignment for springs and stiff springs.

- **Align Parent Space To Path**—(Point-Path constraint only) This option aligns the parent space with the local space of the shape used for the constraint’s path. This is the default parent space alignment for the Point-Path constraint.

---

**Simple Constraints**

The simple constraints provided with reactor are:

- **Spring** *(page 2–727)*
- **Linear Dashpot** *(page 2–730)*
- **Angular Dashpot** *(page 2–732)*

Unlike cooperative constraints, the simple constraint does not require you to add it to a Constraint Solver *(page 2–736)* helper. Instead, reactor adds all valid simple constraints in a scene to the simulation by default. A two-bodied simple constraint is valid if it has two rigid bodies attached, while a single-bodied simple constraint is valid if it has one rigid body attached.

---

**Spring**

<table>
<thead>
<tr>
<th>Create panel &gt; Helpers &gt; reactor &gt; Spring</th>
</tr>
</thead>
<tbody>
<tr>
<td>Menu bar &gt; reactor &gt; Create Object &gt; Spring</td>
</tr>
<tr>
<td>reactor toolbar &gt; Create Spring button</td>
</tr>
</tbody>
</table>

The Spring helper lets you create a spring-like effect between two rigid bodies in the simulation, or between a rigid body and a point in space. During the simulation, the spring exerts forces on the attached bodies in an attempt to maintain its rest length. So, for instance, if the objects are pulled apart so that the spring attachment points are further apart than the rest length, the spring works to bring them back together again.

You can configure a spring’s behavior by specifying its stiffness, damping, and rest length. When not selected, invalid springs will be colored red in the viewport.

You do not have to add a Spring constraint explicitly to a simulation, as all valid springs in a scene are added to the simulation by default. A two-bodied spring is valid if it has two rigid bodies attached, while a single-bodied spring is valid if it has one rigid body attached. When not selected, invalid springs will be colored red in the viewport.

**Procedures**

**To create a spring:**

- Choose one of the above options, and then click in any viewport to add the Spring.
Note: The icon’s position has no effect on the constraint’s behavior.

To attach objects to the spring:
1. Create the Spring and the object(s) to connect using it.
2. If you do not want to assign a second body to the spring, turn off the Parent check box on the spring’s Properties rollout if necessary.
3. Click the Child pick button and then select the object to use as the child object in one of the viewports. This attaches the Spring to the body at the body’s pivot point.
4. If the spring is two bodied, repeat step 2, using the Parent pick button to set the parent object for the spring.

To create the spring and attach the objects in a single step:
• See the Scripts (page 2–817) topic.

To change the attachment positions for the bodies:
1. With the Spring constraint selected, open the Modify panel.
2. In the modifier stack, open the Spring’s sub-object list.
3. Highlight the option corresponding to the object whose attachment point you want to move: Parent Space or Child Space. If the Spring is single-bodied, Parent Space allows you to move the world attachment position.
4. The appropriate space becomes active in the viewport and can be moved using the Move tool. The attachment point maintains its position relative to its corresponding object; for example, if you move the child object, its space, and hence its attachment point, moves with it. The attachment point doesn’t actually have to be on the object.

If you move the attachment points so that they’re inside or beyond the Spring rest length, you will see the attachment points represented by large box markers and the rest length denoted by small box markers. The difference between the two is displayed in red.

5. To reset the attachment point to the object’s pivot, reattach the object to the Spring. Alternatively, if you click the Align Spaces To Each Body button, both attachment points will be reset to their respective body’s pivot.

To align the parent and child constraint spaces:
1. Ensure that the constraint is selected in one of the viewports.
2. In the Align Spaces To group, click the button for your chosen alignment. You can find out more about the alignment options in the Working With Constraint Spaces (page 2–726) section.

Interface

Modifier Stack

<table>
<thead>
<tr>
<th>Spring</th>

</thead>
<tbody>
<tr>
<td>Parent Space</td>
</tr>
<tr>
<td>Child Space</td>
</tr>
</tbody>
</table>

Child Space—At this sub-object level, you can select and move the constraint space for the child object, including the point relative to the child where the Spring is attached to it. When you assign a child body to the Spring, the Child Space attachment point is set to the child’s pivot point. If you alter the position of the attachment point, it maintains its new position relative to the child during the simulation.
**Parent Space**—At this sub-object level, you can select and move the constraint’s second attachment point. If the spring is two-bodied, then this is the point relative to the parent where the spring is attached to it. When you assign a parent object to the Spring, the Parent Space attachment point is set to the parent object’s pivot point. If you alter the position of the attachment point, it maintains its new position relative to the parent. If the spring is single-bodied, then the Parent Space’s attachment point represents the point in the world where the spring is attached.

**Properties rollout**

- **Objects**
  - Parent: None
  - Child: Box01

- **Align Spaces To:**
  - Child Body
  - Parent Body
  - Child Space
  - Parent Space
  - Each Body

- **Lock Relative Transform**

- **Dynamic Properties**
  - Stiffness: 10.0
  - Rest Length: 202.803
  - Damping: 0.1
  - Act on compression
  - Act on extension

- **Disabled**

- **Reset Default Values**

**Parent**—When on, the Spring has two bodies and you can designate an object to be the parent body. When off, the Spring is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.

**Child**—Displays the name of the second rigid body attached to the Spring. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies’ local constraint spaces. You can find out more about each option in the *Working With Constraint Spaces (page 2–726)* section.

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves along with it.

**Stiffness**—The strength of the spring; governs the force the spring applies to each attached body for each unit difference between its current length and its rest length. Values greater than or equal to 0.0 are valid. Default=10.0.

**Rest Length**—The spring applies forces to the attached objects in an attempt to reach this length. You can specify a figure in world units for this value, or you can use the Set button. The spring’s rest length is displayed in the viewports as the length of the displayed line between the two small box markers. The large box markers are the objects’ attachment points.

**Set**—Click this button to set the spring’s rest length to the current distance between the two objects’ attachment points.

**Damping**—Determines how quickly the oscillation of the spring settles down. It governs the forces applied to the connected bodies due to the relative velocities of their connection points. Valid
damping values are those greater than or equal to 0.0. The default damping value is 1.0.

Tip: Typically, a Damping value of 1/10th of the stiffness yields good results.

**Act on compression**—When on, the spring applies forces to the attached objects when its length is less than its Rest Length. Default=on.

**Act on extension**—When on, the spring applies forces to the attached objects when its length is greater than its Rest Length.

**Disabled**—When on, the spring is not used in the simulation.

**Reset Default Values**—Click this to set Stiffness, Rest Length, Damping, Act On Extension, and Act On Compression to their respective default values.

---

**Linear Dashpot**

Dashpots typically server to cushion impact. An example of a real-world linear dashpot is the hydraulic cylinder in an automobile shock absorber. The Linear Dashpot constraint lets you constrain two rigid bodies together in the simulation, or to constrain one body to a position in world space. It behaves like a heavily damped spring with zero rest length. You can specify the strength and damping, and whether collisions between the attached bodies are disabled.

reactor lets you specify a dashpot attachment point in each body’s local space. During the simulation, the dashpot exerts impulses on the attached bodies in an attempt to make these points match up in world space, thus keeping the bodies in the same positions relative to each other. The bodies are still free to rotate around the attachment point.

You do not need to add a Linear Dashpot explicitly to a simulation, as all valid constraints in a scene are added to the simulation by default. A two-bodied dashpot is valid if it has two rigid bodies attached, while a single-bodied dashpot is valid if it has one rigid body attached. When not selected, invalid dashpots are colored red in the viewport.

**Procedures**

**To create a Linear Dashpot:**

- Choose one of the above options, and then click in any viewport to add the dashpot.

  Note: The icon’s position has no effect on the constraint’s behavior.

**To attach objects to the Linear Dashpot:**

1. Create the Linear Dashpot and the objects to connect using it.

2. On the linear dashpot’s Properties rollout, click the Child pick button, and then select the object to use as the child object in one of the viewports. By default, this attaches the linear dashpot to the body at the body’s pivot point.

3. If you do not want to assign a second body to the dashpot, turn off the Parent check box, if necessary.

4. If the dashpot is two-bodied, repeat step 2, using the Parent pick button to set Parent for the Linear Dashpot.

**To create the constraint and attach objects in a single step:**

- See the Scripts (page 2–817) topic.

**To change the attachment positions for the bodies:**

1. With the dashpot selected, open the Modify panel.
2. In the modifier stack open the dashpot’s sub-object list.

3. Highlight the sub-object corresponding to the object in whose space you want to move the attachment point: Parent Space or Child Space. If the dashpot is single-bodied, Parent Space allows you to move the world attachment position.

4. The appropriate point becomes active in the viewport and can be moved using the Move tool. The attachment point maintains its position relative to its corresponding object; for example, if you move the child object, its space, and hence its attachment point, moves with it. The attachment point doesn’t have to actually be on either object.

5. To reset the attachment point to the child object’s pivot, reattach the objects to the dashpot, or use the Align Spaces To Child Body option.

**To align the parent and child constraint spaces:**

1. Ensure that the constraint is selected in one of the viewports.

2. In the Align Spaces To group, click the button for your chosen alignment. You can find out more about the alignment options in the Working With Constraint Spaces (page 2–726) section.

**Interface**

| Allow Interpenetration
| Disabled

| Reset Default Values |
**Parent**—When on, the dashpot has two bodies and you can designate an object to be the parent body. When off, the dashpot is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.

**Child**—Displays the name of the second rigid body attached to the dashpot. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies' local constraint spaces. You can find out more about each option in the *Working With Constraint Spaces* (page 2–726) section.

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves along with it.

**Strength**—Governs the size of the impulse the dashpot applies to each attached body, taking into account the distance between the attachment points. The strength value is mass-dependent. For example, a Strength value of 10 generates a different behavior when connecting two 5 kg bodies than when connecting two 50 kg bodies. Values greater than or equal to 0 are valid for this property. Default=1.

**Damping**—Determines how quickly the oscillation of the linear dashpot settles down. Damping governs the impulse applied to the connected bodies due to the relative velocities of their dashpot connection points. Valid damping values are those greater than or equal to 0 and less than or equal to 100000. Default=0.1.

Tip: Typically, a damping value of 1/10th of the stiffness yields good results.

**Allow Interpenetration**—When on, collisions are disabled between the dashpot’s objects, so that they can pass through each other during the simulation. Defaults=off.

**Disabled**—When on, the dashpot is not added to the simulation.

**Reset Default Values**—Click this to set Strength, Damping, and Disabled to their respective default values.

### Angular Dashpot

Dashpots typically serve to cushion impact. An example of a real-world angular dashpot is a device connected to a door to keep it from slamming shut. You can use the Angular Dashpot constraint to constrain the relative orientation of two rigid bodies, or the absolute orientation of a rigid body in world space. When simulating, the dashpot exerts angular impulses on the bodies to which it is attached in an attempt to maintain the specified rotation between the objects. You can specify the dashpot’s strength and damping, and whether collisions between the system’s bodies are disabled.

An angular dashpot has two sets of axes as sub-objects. For two-bodied dashpots, these are specified as offset rotations from the dashpot’s bodies. For single-bodied dashpots, one sub-object is an offset rotation and the other is a world rotation. In a simulation, the dashpot tries to maintain a common rotation for these axes.

You do not need to add angular dashpots explicitly to a simulation, as all valid dashpots in a scene are added to the simulation by default. A dashpot is valid if it has the correct number of rigid bodies.
attached and is enabled. When not selected, invalid dashpots are colored red in the viewport.

**Procedures**

**To create an Angular Dashpot:**

- Choose one of the above options, and then click in any viewport to add the dashpot.

  *Note: The icon’s position has no effect on the constraint’s behavior.*

**To attach objects to the Angular Dashpot:**

1. Create the dashpot and the objects to connect using it.
2. In the dashpot’s Properties rollout, click the Child pick button and then select the object to use as the child object in one of the viewports. By default, this aligns the Angular Dashpot’s target orientation with the child body’s local space.
3. If you do not want to assign a second body to the dashpot, turn off the Parent check box if necessary.
4. If the dashpot is two-bodied, repeat Step 2, using the Parent pick button to set Parent for the angular dashpot.

**To create the constraint and attach objects in a single step:**

- See the *Scripts (page 2–817)* topic.

**To change the offset rotations for the bodies:**

1. With the Angular Dashpot selected, open the Modify panel.
2. In the modifier stack, open the dashpot’s sub-object list.
3. Highlight the sub-object that corresponds to the offset rotation you want to change: Child Space or Parent Space. If the dashpot is single-bodied, Parent Space represents the world rotation that the dashpot works to align the Child Space with.
4. The selected axis sub-object becomes active in the viewports and can be rotated using the Rotate tool. The axis maintains its offset rotation so that if you rotate the object it’s linked to, it also rotates.
5. To realign the rotation to the child body’s local space, reattach the object to the dashpot. Alternatively, click the Align Spaces To Child Body button.

**To align the parent and child constraint spaces:**

1. Ensure that the constraint is selected in one of the viewports.
2. In the Align Spaces To group, click the button for your chosen alignment.

  You can find out more about the alignment options in the *Working With Constraint Spaces (page 2–726)* section.

**Interface**

**Modifier Stack**

- **Angular Dashpot**
  - **Parent Space**
  - **Child Space**

**Child Space**—At this sub-object level, you can select and rotate the offset rotation for the child object. This is the rotation that the angular dashpot tries to maintain for the child body relative to the parent. When you assign a child object to the dashpot, reactor aligns Child Space to the child body’s local space. If you alter the rotation of this sub-object, it maintains its new rotation relative to the child body.
**Parent Space**—At this sub-object level, you can select and rotate the offset rotation for the parent body. This is the rotation that the dashpot tries to maintain for the parent body relative to the child. When you assign the parent body to the dashpot, this rotation is aligned with the child body’s local space. If you alter the rotation of this sub-object, it maintains its new rotation relative to the parent. If the dashpot is single-bodied, this rotation represents the world rotation to which the dashpot tries to align the Child Space axis.

**Properties rollout**

**Parent**—When on, the dashpot has two bodies and you can designate an object to be the parent body. When off, the dashpot is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.

**Child**—Displays the name of the second rigid body attached to the dashpot. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies’ local constraint spaces. You can find out more about each option in the *Working With Constraint Spaces* (page 2–726) section.

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves along with it.

**Strength**—Governs the size of the impulse the dashpot will apply to each attached body, taking into account the difference in their relative offset rotations (Child Space and Parent Space). The strength value is mass dependent – for example, a strength value of 10 will generate a different behavior when connecting two 5 kg bodies than when connecting two 50 kg bodies. Values greater than or equal to 0.0 are valid for this property. Default=1.0.

**Damping**—This value affects how quickly the oscillation of the angular dashpot settles down. It governs the impulse applied to the connected bodies due to their relative angular velocities. Valid damping values are those greater than or equal to 0. Default=0.1.

Tip: Typically, a damping value of 1/10th of the stiffness yields good results.

**Allow Interpenetration**—When on, collisions are disabled between the dashpot’s objects: During the simulation, they can pass through each other. Default=off

**Disabled**—When on, the dashpot is not added to the simulation.

**Reset Default Values**—Click this to set Strength, Damping, and Disabled to their respective default values.
Cooperative Constraints

Cooperative constraints are more stable than simple constraints (page 2–727), but can be more computationally expensive to simulate. For a cooperative constraint to take part in the simulation, you first need to add it to a Constraint Solver (page 2–736). The solver acts as a container for the cooperative constraint in a particular Rigid Body Collection, and performs all the calculations necessary for the constraints to work together.

The following constraint types are cooperative constraints:
- Hinge (page 2–747)
- Point-Point constraint (page 2–750)
- Point-Path constraint (page 2–762)
- Car-Wheel constraint (page 2–757)
- Prismatic constraint (page 2–754)
- Rag Doll constraint (page 2–737)

Common Properties
The following properties are shared by all cooperative constraints:

Strength and Tau
These properties govern the impulses applied to the constraint’s bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement.

Strength—The constraint applies an impulse to each attached body in order to maintain the constraint, based on the relative velocities of the attached bodies. The Strength parameter governs the percentage of this impulse the constraint will apply to each object. If this is sufficient, then the constraint is maintained.

Tau—if the constraint drifts; that is, if the attached objects reach a state where the constraint isn’t satisfied, then reactor applies a corrective force to rectify this drift. An impulse is calculated to rectify the drift in a constraint system; the Tau parameter governs the percentage of the corrective impulse the constraint applies to each object.

Note: Tau is unavailable in the Havok 3 engine.

Breakable Constraints
A breakable constraint stops working when a specified threshold is exceeded. For example, you could use a breakable constraint to make a door that flies off its hinges when kicked hard enough. You make a constraint breakable by turning on its Breakable check box. It then ceases to exert impulses on its constrained bodies if its limits are exceeded during the simulation.

Breakable—Turn on to make the constraint breakable.

The Linear and Angular parameters apply only to Havok 1, and the Threshold parameter applies only to Havok 3.

Linear—The maximum linear impulse the breakable constraint can apply before it breaks. Available in Havok 1 only.

Angular—The maximum angular impulse the breakable constraint can apply before it breaks. Available in Havok 1 only.

Threshold—A generic impulse parameter that governs the overall breakability of the constraint. Larger values make the constraint harder to break. Available in Havok 3 only.
Chapter 13: reactor

**Constraint Solver**

Create panel > Helpers > reactor > CSolver

Menu bar > reactor > Create Object > Constraint Solver

reactor toolbar > Create Constraint Solver button

The Constraint Solver acts as a container for the cooperative constraints (page 2–735) in a particular Rigid Body Collection (page 2–723), and performs all the calculations necessary for the constraints to work together.

For a cooperative constraint to be simulated in a scene, it must be included in a valid Constraint Solver and any of the rigid bodies it contains should be in the Rigid Body Collection associated with the solver. For a Constraint Solver to be valid it should be associated with a valid Rigid Body Collection. When not selected, an invalid Constraint Solver is red in the viewport.

You can disable an entire Constraint Solver, thus disabling all of its constraints. You can also set a deactivation threshold for all the constraints in the solver, which lets you specify when you would like all the relevant rigid bodies to be deactivated.

**Procedures**

**To create a Constraint Solver:**

- Choose one of the above options, and then click in any viewport to add the Constraint Solver.

  *Note*: The icon's position has no effect on the constraint's behavior.

**To assign a Rigid Body Collection to the solver:**

1. On the Properties rollout click the RB Collection button.

   This enters a pick mode in which you can choose only a Rigid Body Collection.

2. In one of the viewports click the collection to assign to the Constraint Solver. The collection should contain the rigid bodies for the constraints in the solver.

**To add constraints to a solver:**

1. Create a Constraint Solver and some cooperative constraints to add to the solver.

2. Add constraints to the solver using either (or both) of these methods:

   * On the Constraint Solver > Properties rollout, click the Pick button, and then in the viewport click a constraint helper to add.
   * On the Properties rollout, click the Add button, and then use the dialog to specify one or more constraints to add.
**Interface**

Properties rollout

- **RB Collection button**—Displays the name of the Rigid Body Collection assigned to the solver, if any. To assign a Rigid Body Collection to the solver, click this button and then selecting a collection in any viewport.

- **Highlight**—Click this button to cause the constraints in the Constraints list to momentarily display in the viewports as if selected.

- **Constraints**—Lists the names of the constraints currently in the solver.

- **Pick**—Lets you add a constraint to the solver. Click this button, then in the viewport move the cursor over the constraint you would like to add to the solver. If the object can be used as a constraint, the cursor changes from an arrow to a cross and you can select the object to add it to the solver.

- **Add**—Lets you add one or more constraints from the scene to the solver. Click the button to open up the Select New Constraints To Add dialog. Make a selection in the provided list, and then add the constraints to the solver by pressing the Select button.

- **Delete**—Lets you remove constraints from the solver. Highlight the constraints to remove from the solver in the Constraints list and then click this button.

- **Deactivation Threshold**—Lets you specify a special deactivation threshold for all the rigid bodies constrained by the solver’s constraints. Objects in a Constraint Solver are activated and deactivated together; this parameter specifies how aggressive the deactivation is. A value of 0.0 disables deactivation. For more information about deactivation, see Havok 1 World/Havok 3 World Rollout (page 2–808).

- **Disabled**—When on, disables all the constraints in this solver.

- **Reset Default Values**—Sets Deactivation Threshold and Disabled to their respective default values.

---

**Rag Doll Constraint**

Create panel > Helpers > reactor > Ragdoll

Menu bar > reactor > Create Object > Rag Doll Constraint

reactor toolbar > Create Rag Doll Constraint button

The Rag Doll constraint lets you realistically simulate the behavior of body joints, such as hips, shoulders, and ankles. Once you decide the degree of movement a joint should have, you can model it by specifying limiting values for the Rag Doll constraint.
Chapter 13: reactor

The Rag Doll constraint uses the parent body as a reference when defining the limits for the motion of the child body. For example, when your torso moves, your arm always moves with it. So when modeling a shoulder joint, you would usually designate the torso as the parent body and the upper arm as the child body. You can then specify limits on the arm’s movement relative to the torso, as in the above illustration: The arm is allowed to rotate relative to the torso within the grey limited cone. You can also limit the child body’s ability to twist.

You restrict how a Rag Doll constraint’s child can move relative to the parent using the constraint’s Twist, Cone, and Plane limits (page 2–742). As with the other constraints, the constraint space for the Rag Doll joint is defined in each body’s local space; you use this constraint space to define your limits. The constraint space is defined as follows:

- The origin as the attachment point of the constraint between the child and parent bodies.
- A twist axis, which is the axis around which the child body can twist relative to the parent body. You use this axis to specify twist limits and the child body’s permitted cone of movement.
- A plane and plane normal centered on the attachment point; the plane serves to define further limits that restrict the child body’s movement within the cone.

reactor provides special limit visualizations to help you choose appropriate values for the Rag Doll.

For a detailed explanation of how to define those limits, see Defining Rag Doll Limits (page 2–743). reactor simulates a Rag Doll constraint if it has the correct number of rigid bodies attached and is included in a valid Constraint Solver (page 2–736). When not selected, invalid rag dolls are red in the viewport.

To find out how to create an example character quickly using the Rag Doll constraint, see Scripts (page 2–817).

Procedures

To create a Rag Doll constraint:

- Choose one of the above options, and then click in any viewport to add the Rag Doll.

Note: For a two-bodied Rag Doll, the icon’s initial position has no effect on the Rag Doll’s behavior. For a single-bodied Rag Doll, it defines the initial position of the world attachment point. You can change this afterwards.

To attach objects to the Rag Doll:

1. Create the rag doll and the objects to connect using it.

2. In the rag doll’s Properties rollout, click the Child pick button. Now, in one of the viewports, select the object to use as the child object. This attaches the constraint to the selected body at the body’s pivot point. The twist axis for the constraint in the child’s space is aligned to the x-axis of the child object and initially, the plane normal will be aligned to the y-axis.
This constraint is more intuitive to use if the child and parent bodies are attached correctly. For example, if connecting an upper arm to a shoulder, the shoulder should be the parent and the upper arm the child.

3. If you do not want to assign a parent to the constraint, turn off the Parent check box.

4. If the constraint is two bodied, repeat Step 2, using the Parent pick button to set the parent body for the constraint. By default, the constraint space in the parent’s local space is also aligned with the child body.

To create the constraint and attach objects in a single step:

• See the Scripts (page 2–817) topic.

To change the Rag Doll positions and orientations for the bodies:

1. With the Rag Doll selected, open the Modify panel.

2. In the modifier stack open the sub-object list.

3. Access the sub-object level corresponding to the object whose constraint representation is to be altered: Parent Space or Child Space. If the rag doll is single-bodied, Parent Space represents the world attachment position and rotation of the rag doll’s axes.

4. The space, represented by just the twist axis for the child and by the twist axis, plane normal and limit visualization for the parent, becomes active in the viewport and can be moved and rotated using the Move and Rotate tools respectively. The space maintains its position and rotation relative to its corresponding object. For example, if you move or rotate the child, Child Space moves relative to it.

5. To reset the space for an object to its default, reattach the object to the rag doll or use the Align To Child Body button.

6. You can also rotate the plane normal independent of the twist axis. To do this, set the sub-object level to Plane Rotation and you will be able to rotate the plane normal with respect to the parent’s twist axis.

To change the Cone and Plane limits:

1. Ensure that you can see the limit visualization for the Rag Doll; this helps you to choose appropriate limits for your desired behavior. Visual representation of the limits is displayed at the location of the parent’s sub-object. This provides you with a graphical representation of the limited area of movement for the child relative to the parent.

2. With the rag doll selected, open the Properties rollout.

Note: You can use this rollout to specify how the limits are represented in the visualization, as well as changing the limits.
3. Change the Cone > Min and Max settings.
   When displayed, the cone remains symmetrical and is rotated about the plane normal by the average offset of Min and Max. For example, if Min=-10.0 and Max=20.0, the average offset is (-10+20)*0.5=5 with a cone angle of 15. In effect, we have a 15-degree symmetrical cone [-15, 15] rotated by 5 degrees, resulting in limits of [-10, 20]. If the plane normal is not at 90 degrees to the twist axis, non-intuitive cone rotations can result. The rotation of the twist axis for the attached object is limited to the volume of this cone. You can view the cone on its own by ensuring that only the Show Cone option in the Properties rollout > Display group is on.

4. You can also try changing the Plane > Min and Max settings. These are limited between [-90, 0] and [0,90] respectively. Taking the Min and Max limits and sweeping those angles around the plane normal creates cones. The rotation of the attached object is then limited to within the region between the plane and these cones.

5. By combining Cone and Plane limits you generate valid rotational regions for the child object relative to the parent object. This is the region represented by the Show Volume option. Note: Cone and plane limits limit the movement independently. As a result, it is possible to have ineffective plane limits, where the cones generated by the plane limits do not intersect the cone generated by the cone limits. Use the plane limits to reduce the level of movement provided by the cone.

To change the Twist limits:
1. Select the Rag Doll helper object and open the Properties rollout.
2. The Twist settings limit the rotation of the child object about the twist axis relative to the parent object. To fix the twist of one object relative to the other, set the twist limits to [0,0].
3. Display the Twist limits by turning on Display rollout > Show Twist.

For a detailed explanation of how to define these limits, see Defining Rag Doll Limits (page 2–743).
Interface

Modifier Stack

- Parent Space
- Child Space
- Plane Rotation

**Parent Space**—At this sub-object level, you can move and rotate the representation of the Rag Doll for the parent body. The constraint axes are defined in the parent body’s space, which means that if you alter the position or rotation of the parent, the space moves as well and maintain its offset rotation and translation with respect to the parent. When you assign a parent body to the Rag Doll, Parent Space is also aligned with the child body’s local space, with the attachment point at the child body’s pivot point, the twist axis aligned with the child’s X axis, and the plane normal aligned to the child’s Y axis. If the Rag Doll is single-bodied, then Parent Space represents the world orientation and position of the constraint.

**Child Space**—At this sub-object level, you can move and rotate the representation of the Rag Doll for the child body. The constraint axes are defined in the child body’s space, which means that if you alter the position or rotation of the child, the space moves as well and maintain its offset rotation and translation with respect to the child. When you assign a child body to the Rag Doll, the Child Space is positioned so that the attachment point coincides with the child body pivot point, and the twist axis is aligned with the child’s X axis.

**Note:** While the Child Space sub-object has its own representation of the plane and plane normal, these are not displayed at this sub-object level, as the plane normal can be edited only in the parent body’s space.

**Plane Rotation**—This sub-object level allows independent rotation of the plane normal with respect to the Parent Space. This means that your plane normal doesn’t have to be perpendicular to your twist axis, allowing for a greater range of constraint setups. However, it should be noted that non-orthogonal systems affect the way reactor handles non-symmetrical cone limits.
Properties rollout

Parent—When on, the Rag Doll has two bodies and you can designate an object to be the parent body. When off, the Spring is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.

Child—Displays the name of the second rigid body attached to the Rag Doll. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

Align Spaces To—Use these options to align the bodies’ local constraint spaces. You can find out more about each option in Working With Constraint Spaces (page 2–726).

Lock Relative Transform—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves along with it.

Strength group

Strength/Tau—Govern the impulses applied to the constraint’s bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement. You can find out more about these parameters in Strength and Tau (page 2–735).

Limits group

Twist Min—The minimum rotation about the twist axis the constraint allows between the reference and attached objects’ constraint spaces. For example, if Min=–5 then, with respect to the constraint spaces, the child cannot rotate more than 5 degrees counterclockwise about the twist axis.

Twist Max—The maximum rotation about the twist axis the constraint allows between the reference and attached objects’ constraint spaces. For example, if Max=5 then, with respect to the
Defining Rag Doll Limits

Constraint spaces, the child cannot rotate more than 5 degrees clockwise about the twist axis.

**Cone Min**—The minimum value, in degrees, used to specify the limit cone. This value combines with the Cone Max value to generate a symmetrical cone. This cone is rotated about the plane normal by an offset calculated by combining these limits. The rotation of the child’s twist axis is then limited to the volume of this cone with respect to the parent.

For example, if the Min=-10 and Max=20, the range is 30 degrees. A 30-degree cone [-15,15] is created about the twist axis and is then rotated by the offset between the limits (-10+20)*0.5=5. This results in the effective limits being [-15,15] rotated by 5 degrees, thus final limits of [-10, 20].

**Cone Max**—The maximum value, in degrees, used to specify the limit cone. This is combined with the Cone Min value to generate a symmetrical cone. This cone is rotated about the plane normal by an offset calculated by combining these limits. The rotation of the child’s twist axis is then limited to being within this cone with respect to the parent.

**Plane Min**—The angle between the plane and a reference line in the range [-90,0]. This line is swept about the plane normal to create a cone. The child’s twist axis is then restricted from entering this cone. If this cone intersects the cone produced by the cone limits, it further inhibits the motion of the child with respect to the parent.

**Plane Max**—The angle between the plane and a reference line in the range [0,90]. This line is swept about the plane normal to create a cone. The child’s twist axis is then restricted from entering this cone. If this cone intersects the cone produced by the cone limits, it further inhibits the motion of the child with respect to the parent.

**Breakable group**

**Breakable**—When on, the constraint is breakable. If its breakable limits are exceeded during simulation it will cease to exert impulses on the attached objects. You can find out more about breakable constraints in *Breakable Constraints* (page 2–735).

**Display group**

**Show Twist**—When on, Twist limits display as part of the Parent Space visualization. The representation is a cylinder section showing the restricted motion of the attached object with respect to rotation about the twist axis.

**Show Cone**—When on, the entire symmetrical cone produced by the Cone > Min and Max limits displays as part of the Parent Space visualization.

**Show Plane**—When on, representations of the plane and plane normal display as part of the Parent Space visualization.

**Show Plane Limits**—When on, the cones formed by the plane limits display as part of the Parent Space visualization.

**Show Volume**—If true, a representation of the allowed region of movement based on a combination of the plane and cone values will be calculated and displayed as part of the Parent Space visualization.

**Size**—Allows you to change the size of the limit visualization in the viewport.

**Reset Default Values**—Resets the parameters for this constraint to their default values.

---

**Defining Rag Doll Limits**

The *Rag Doll constraint* (page 2–737) is useful for simulating complex joints, like those found in some human and animal joints (shoulders, hips), that cannot be properly simulated by simpler
constraints like Hinge (page 2–747) or Point-Point (page 2–750) constraints.

Because they represent complex joints, the rotational limits use a complex parameterization that can benefit from some explanation. This section covers the different axes, planes, and cones used for that parameterization. We'll begin with a simple picture of two objects connected by a rag doll constraint; you can think of a shoulder joint, where the parent body is the torso and the child body the upper arm:

The illustration shows three axes of importance: the Twist Axis, the Plane Axis and the Twist X Plane Axis. The twist axis is probably the easiest to visualize and you can do so by simply stretching out your arm and rotating it so that your thumb changes from pointing upwards to downwards. Your movement is just a series of rotations along the twist axis of the shoulder and elbow. In general, the twist axis should follow the length of the child body in a joint. In reactor you can specify the extent to either side of the neutral position the constraint can twist; this need not be symmetrical.

The other two axes are interlinked and together control the volume the child body may occupy. So first we'll look at the cone angles that allow you to specify the volume that the child may move through:
Defining Rag Doll Limits

If you imagine the constraint representing your shoulder, then the green volume is the range of allowed positions your upper arm may occupy. However, we can refine the allowed volume further by using the plane axis to enforce plane limits. These limits are used to generate two further cones:

- A. Twist Axis
- B. Plane Axis
- C. Twist X Plane Axis
  1. Plane Min.
  2. Plane Max. Cone

A. Twist Axis
B. Plane Axis (inward)
C. Twist X Plane Axis
1. Cone Min.
2. Cone Max.

These limits are used to generate two further cones:

A. Twist Axis
B. Plane Axis
C. Twist X Plane Axis (outward)
1. Plane
2. Plane Min. Cone
3. Plane Max. Cone
4. Plane Min.
5. Plane Max.
This allows us to create two different scenarios: one where the cones generated by the plane limits intersect with cone produced by the cone angles, and another where they do not:

If the volumes do not intersect, the plane limits have no effect in the constraint. However, by allowing the cones to intersect, and deeming the overlapping volume as invalid body positions, we can limit the allowed positions for the child body even further:
The Hinge constraint allows you to simulate a hinge-like action between two bodies. reactor lets you specify an axis in local space for each body, with a position and a direction. During the simulation, the two axes attempt to match position and direction, thereby creating an axis around which the two bodies can rotate. Alternatively, you can hinge a single body to an axis in world space.

You can also limit the rotation between the attached objects relative to the hinge axis, allowing you, for instance, to create a door that can open only to a specified extent. You define this limitation with respect to an axis perpendicular to the hinge axis for each body.

A Hinge constraint is simulated only if it has the correct number of rigid bodies attached and is included in a valid Constraint Solver (page 2–736). When not selected, an invalid Hinge is red in the viewport.

**Procedures**

To create a Hinge constraint:

- Choose one of the above options, and then click in any viewport to add the Hinge constraint.
  
  **Note:** The icon’s position has no effect on the constraint’s behavior.

To attach objects to the Hinge:

1. Create the Hinge and the objects to connect using it.

2. On the Hinge’s Properties rollout, click the Child pick button, and then select the object to use as the child object in one of the viewports. By default, this attaches the constraint so that its axis goes through the child body pivot point and the axes are aligned with the child body’s local space. The constraint axis is aligned with the child’s Z axis, and the perpendicular axis used for rotation limits is aligned to the child’s X axis.

3. If you do not want to assign a second body to the Hinge, turn off the Parent check box if necessary.

4. If the Hinge is to be two-bodied, repeat step 2, using the Parent pick button to set Parent for the Hinge.
To create a Hinge and attach objects in a single step:

- See the Scripts (page 2–817) topic.

To change the Hinge positions and rotations for the bodies:

1. With the Hinge helper object selected, open the Modify panel.
2. In the modifier stack open the sub-object list for the Hinge.
3. Access the sub-object level corresponding to the object whose hinge axes you want to move: Child Space or Parent Space. If the Hinge is single-bodied, Parent Space represents the world attachment position and rotation of the axes.
4. The space, represented by a pair of axes, the larger of which represents the hinge axis, the smaller of which is used to specify limits, becomes active in the viewport. It can be moved and rotated using the Move and Rotate tool respectively. The space maintains its position and rotation relative to its corresponding object. For example, if you move or rotate the child body, the Child Space moves with it.
5. To reset the axes to their default alignment, reattach the objects to the Hinge or click the Align Spaces To > Child Body button.

To limit the rotation between the attached objects:

1. With the Hinge selected, open the Properties rollout.
2. Turn on the Limited check box. The Hinge limits display around the Parent Space axis. The default angle limits are –90.0 and 90.0. This means that in a situation where the sub-objects are fully aligned for the objects, the objects will be able to rotate 90 degrees in either direction about the shared hinge axis. The child object is free to rotate within the indicated limits relative to the parent during the simulation.
3. Change the minimum and maximum rotations the constraint maintains between the objects by adjusting the Min Angle and Max Angle values. The limit display updates to reflect your changes, to help you choose appropriate values. Upon simulation you can see that the rotation between the objects has been limited.

### Interface

**Modifier Stack**

- **Hinge**
  - **Parent Space**
  - **Child Space**

**Parent Space**—At this sub-object level, you can move and rotate the representation of the Hinge for
the parent body. The Hinge axes are defined in the parent body’s space, which means that if you alter the position or rotation of the parent, the space moves as well and maintains its offset rotation and translation with respect to the parent. When you assign a parent body to the Hinge, Parent Space is also aligned with the child body’s local space, with the Hinge axis going through the child body’s pivot point. If the Hinge is single-bodied, then Parent Space represents the world orientation and position of the Hinge.

**Child Space**—At this sub-object level, you can move and rotate the representation of the Hinge for the child body. The Hinge axes are defined in the child body’s space, which means that if you alter the position or rotation of the child, the space moves as well and maintains its offset rotation and translation with respect to the child. When you assign a child body to the Hinge, the Child Space hinge axis is positioned so that it goes through the child body pivot point, and the axes are aligned with the child body’s local space: The Hinge axis is aligned with the child’s Z axis, and the perpendicular axis used for rotation limits is aligned to the child’s X axis.

**Properties rollout**

- **Parent**—When on, the Hinge has two bodies and you can designate an object to be the parent body. When off, the Hinge is single-bodied and the point occupied by the Parent Space sub-object is the parent.

  You assign the parent object by clicking this button and then selecting a rigid body from any viewport.
Thereafter the button displays the name of the parent body.

**Child**—Displays the name of the second rigid body attached to the Hinge. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies' local constraint spaces. You can find out more about each option in *Working With Constraint Spaces* (page 2–726).

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves and rotates along with it, and vice-versa.

**Strength group**

**Strength/Tau**—Govern the impulses applied to the constraint's bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement. You can find out more about these parameters in *Strength and Tau* (page 2–735).

**Limited group**

**Limited**—When on, limits the rotation about the hinge axis between the attached objects. When this value is true, the child object will only be free to rotate relative to the parent within the range specified by the Min Angle and Max Angle values. You can also specify a friction value for a limited Hinge.

**Min Angle**—The minimum rotation the constraint allows between the two hinge spaces. For example, if Min Angle is –5.0 then the child body cannot rotate more than 5 degrees counter clockwise about the hinge axis relative to the parent body.

**Max Angle**—The maximum rotation the constraint allows between the two hinge spaces. For example, if Max Angle is 5.0 then the child body cannot rotate more than 5 degrees clockwise about the hinge axis relative to the parent body.

**Friction**—The level of friction applied to the objects as they try to rotate about the hinge axis. It is only applied to limited Hinges.

**Breakable group**

**Breakable**—When on, the constraint is breakable. If its breakable limits are exceeded during simulation, it ceases to exert impulses on the attached objects. You can find out more about breakable constraints in *Breakable Constraints* (page 2–735).

**Display group**

**Size**—Lets you change the size of the Hinge limit display in the viewport.

**Reset Default Values**—Returns the Strength, Tau, Min Angle, Max Angle, Friction, Linear, Angular, Threshold, and Display settings to their default values.

---

**Point-Point Constraint**

Create panel > Helpers > reactor > Point-Point Constraint

Menu bar > reactor > Create Object > Point-Point Constraint

reactor toolbar > Create Point-Point Constraint button

The Point-Point (point-to-point) constraint lets you attach two objects together, or an object to a point in world space. It forces its objects to try to share a common point in space. The objects can rotate freely relative to each other, but always have the attachment point in common. When you set up the constraint, the point is defined in the object space of each object involved. During the simulation the constraint tries to apply forces to the objects so that the two pivot points defined by the two objects match.
reactor also provides two variations on the Point-Point constraint: Limited and Stiff Spring. With a Limited Point-Point constraint, you can specify limits for how much the child object can rotate relative to the parent. A Stiff Spring constraint is similar to a standard Point-Point constraint with one important exception: It holds the constrained bodies apart at a specified distance, as if they were attached at each end of an invisible rod. The Stiff Spring variant requires a point in the body space of each of two bodies, and a constant distance by which reactor must keep these two points separated. Each body is free to rotate around its point.

The constraint is simulated when it has the correct number of rigid bodies attached and is included in a valid Constraint Solver (page 2–736). When not selected, an invalid Point-Point constraint is red in the viewport.

Procedures

To create a Point-Point constraint:

- Choose one of the above options, and then click in any viewport to add the Point-Point constraint.

  Note: The icon’s position has no effect on the constraint’s behavior.

To attach objects to the Point-Point constraint:

1. Create the constraint and the objects to connect with it.

2. On the constraint’s Properties rollout, click the Child pick button, and then select the object to use as the child object in one of the viewports. By default, this attaches the constraint to the body at the body’s pivot point.

3. If you do not want to assign a second body to the constraint, turn off the Parent check box if necessary.

4. If the constraint is to be two-bodied, make sure Parent is on and then use the Parent pick button to set the parent for the constraint. By default, the attachment point for the parent is also aligned with the child body’s pivot point, which means that the bodies will maintain their current positions relative to each other in the simulation.

To create the constraint and attach objects in a single step:

- See the Scripts (page 2–817) topic.

To change the attachment positions for the bodies:

1. With the constraint selected, open the Modify panel.

2. In the modifier stack open the constraint’s sub-object list.

3. Access the sub-object level corresponding to the object in whose space you want to move the attachment point: Parent Space or Child Space. If the constraint is single-bodied, Parent Space allows you to move the world attachment position.

4. The corresponding point becomes active in the viewports and can be moved using the Move tool.

  The attachment point maintains its position relative to its corresponding object. For example, if you move the child object, its space, and hence its attachment point, moves with it. The attachment point doesn’t have to actually be on either object.

5. To reset the attachment point to the child object’s pivot, reattach the objects to the constraint, or click the Align Spaces To > Child Body button.

To limit the rotation between the attached objects:

1. With the constraint selected, open the Properties rollout.
2. In the Constraint Type group, choose Limited.
   By default, the child body can rotate a total of 90 degrees around each axis relative to the parent during the simulation: 45 degrees clockwise and 45 degrees counterclockwise.

3. You can then choose which limits to display around the Parent Space constraint axis by turning on each one’s check box.

4. If you then change the limits, the limit display updates to reflect your changes to help you choose appropriate values. Upon simulation you can see that the rotation between the objects has been limited.

5. You can also change the orientation of the axis to be limited by rotating the Child Space and Parent Space sub-objects.

To create a Stiff Spring constraint:

1. With a Point-Point constraint selected, open the Properties rollout.

2. In the Constraint Type group, choose Stiff Spring.

3. You can now specify a Length value for the stiff spring. The default is 0.0: the same as a Point-Point constraint.

During the simulation, reactor works to maintain this distance between the constrained objects’ attachment points. To use the current distance between the attachment points as the length, click the Set button.

**Interface**

**Modifier Stack**

<table>
<thead>
<tr>
<th>Modifier Stack</th>
</tr>
</thead>
<tbody>
<tr>
<td>Point-Point</td>
</tr>
<tr>
<td>Parent Space</td>
</tr>
<tr>
<td>Child Space</td>
</tr>
</tbody>
</table>

**Parent Space**—At this sub-object level, you can select and move the constraint attachment point in the parent body’s local space. When you assign a parent object to the constraint, the Parent Space attachment point is set to the child object’s pivot point. If you alter the position of the Parent Space attachment point, it maintains its new position relative to the parent during the simulation. If the constraint is single-bodied, the Parent Space’s position represents the point in the world where the constraint is attached.

**Child Space**—At this sub-object level, you can select and move the constraint attachment point in the child body’s local space. When you assign a child body to the constraint, the Child Space attachment point is set to the child object’s pivot point. If you alter the position of the Child Space attachment point, it maintains its new position relative to the child during the simulation.
Properties rollout

**Parent**—When on, the constraint has two bodies and you can designate an object to be the parent body. When off, the constraint is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.

**Child**—Displays the name of the second rigid body attached to the constraint. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies’ local constraint spaces. You can find out more about each option in *Working With Constraint Spaces (page 2–726)*.

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves and rotates along with it, and vice-versa.

**Strength group**

**Strength/Tau**—Govern the impulses applied to the constraint’s bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement. You can find out more about these parameters in *Strength and Tau (page 2–735)*.

**Constraint Type group**

These options let you choose the type of Point-Point constraint to add to your scene.

- **Standard**—The default option.
- **Limited**—This type allows you to limit how the child object can rotate relative to the parent.
- **Stiff Spring**—This type allows you to specify a distance for reactor to maintain between the constraint attachment points.

**Limited (Limited constraints only)**—Lets you specify how much the child object can rotate relative to
Chapter 13: reactor

the parent around the x, y, and z axes - for each axis there is a minimum (counterclockwise) and maximum (clockwise) limit. You can use the check boxes to switch on or off the limit displays in the viewport.

**Length (Stiff Springs only)**—The distance that reactor should maintain between the constraint attachment points.

**Set**—Sets Length to the current distance between the attachment points.

**Breakable group**

**Breakable**—When on, the constraint is breakable. If its breakable limits are exceeded during simulation, it ceases to exert impulses on the attached objects. You can find out more about breakable constraints in *Breakable Constraints* (page 2–735).

**Display group**

**Size**—Lets you change the size of the constraint limit display in the viewport.

**Reset Default Values**—Returns the constraint’s parameters to their default values.

---

**Prismatic Constraint**

Create panel > Helpers > reactor > Prismatic

Menu bar > reactor > Create Object > Prismatic Constraint

reactor toolbar > Create Prismatic Constraint button

The Prismatic constraint serves as a constraint between two rigid bodies, or a rigid body and the world, that allows its bodies to move relative to each other along one axis only. Rotations, as well as the remaining two translation axes, are fixed. For example, you could use a Prismatic constraint when creating a forklift truck.

A Prismatic constraint is simulated if it has the correct number of rigid bodies attached and is included in a valid Constraint Solver (page 2–736). When not selected, an invalid prismatic constraint is red in the viewport.

**Procedures**

**To create a Prismatic constraint:**

- Choose one of the above options, and then click in any viewport to add the Prismatic constraint.
  - Note: The icon’s position has no effect on the constraint’s behavior.

**To attach objects to the prismatic constraint:**

1. Create the Prismatic constraint and the objects to connect using it.
2. On the constraint’s Properties rollout, click the Child pick button and then, in one of the viewports, select the object to use as the child. This attaches the constraint to the body at the body’s pivot point. The constraint’s sliding axis is aligned to the Z axis of the object.
3. If you do not want to assign a second body to the prismatic constraint, turn off the Parent check box, if necessary.
4. If the constraint is to be two-bodied, make sure Parent is on and then use the Parent pick button to set the parent for the constraint.

**To create the constraint and attach objects in a single step:**

- See the *Scripts* (page 2–817) topic.

**To change the Prismatic constraint positions and rotations for the bodies:**

1. With the constraint selected, open the Modify panel.
2. In the modifier stack open the constraint’s sub-object list.
3. Access the sub-object level corresponding to the object whose attachment point you want to move: Child Space or Parent Space. If the constraint is single-bodied, Parent Space represents the world attachment position and rotation of the constraint axes.

4. The space, represented by a pair of axes, the larger of which represents the sliding axis, becomes active in the viewport and can be moved or rotated using the Move or Rotate tool, respectively. The space maintains its position and rotation relative to its corresponding object. For example, if you move or rotate the child body, Child Space moves with it.

5. To realign the constraint space to the child body, reattach the object to the Prismatic constraint, or choose the Align To Child Body option.

To limit the movement of the child body along the sliding axis:

1. With the constraint selected, open the Properties rollout.

2. Turn on the Limited check box.

Both Limit parameters (Min and Max) are set by default to 0.0. This means that from a situation where the sub-objects are fully aligned for the objects, the child can move 0 units in either direction along the shared sliding axis relative to the parent.

The limits are displayed as a line in Parent Space.

3. Change the Min Limit and Max Limit settings as necessary.

<tbody>
<tr>
<td>Parent Space</td>
</tr>
<tr>
<td>Child Space</td>
</tr>
</tbody>
</table>

Parent Space—At this sub-object level, you can move and rotate the representation of the Prismatic constraint for the parent body. The constraint axes are defined in the parent body’s space, which means that if you alter the position or rotation of the parent, the space moves as well and maintains its offset rotation and translation with respect to the parent. When you assign a parent body to the constraint, Parent Space is also aligned with the child body’s local space, with the constraint axis going through the child body’s pivot point. If the constraint is single-bodied, then Parent Space represents the world orientation and position of the constraint.

Child Space—At this sub-object level, you can move and rotate the representation of the Prismatic constraint for the child body. The constraint
axes are defined in the child body’s space, which means that if you alter the position or rotation of the child, the space moves as well and maintains its offset rotation and translation with respect to the child. When you assign a child body to the constraint, the Child Space axis is positioned so that it goes through the child body pivot point, and the axes are aligned with the child body’s local space: The prismatic sliding axis is aligned with the child’s Z axis.

**Properties rollout**

- **Parent**—When on, the constraint has two bodies and you can designate an object to be the parent body. When off, the constraint is single-bodied and the point occupied by the Parent Space sub-object is the parent.
You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.

**Child**—Displays the name of the second rigid body attached to the constraint. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies' local constraint spaces. You can find out more about each option in Working With Constraint Spaces (page 2–726).

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves and rotates along with it, and vice-versa.

**Strength group**

**Strength/Tau**—Govern the impulses applied to the constraint's bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement. You can find out more about these parameters in Strength and Tau (page 2–735).

**Limited group**

**Limited**—When on, limits the movement of the child object along the sliding axis; the child object can move relative to the parent only within the range specified by the Min Limit and Max Limit values. You can also specify a Friction value for a limited prismatic constraint.

**Min Limit**—The minimum distance the constraint allows between the two spaces. For example, if Min Limit is -5.0 then the child body then the child object cannot move more than 5 units backwards relative to the parent along the sliding axis.

**Max Limit**—The maximum distance the constraint allows between the two spaces. For example, if Max Limit is 5, then the child object will not be able to move more than 5 units forward relative to the parent along the sliding axis.

**Friction**—The level of friction applied to the objects as they try to move along the sliding axis. It is applied only to limited Prismatic constraints.

**Breakable group**

**Breakable**—When on, the constraint is breakable. If its breakable limits are exceeded during simulation, it ceases to exert impulses on the attached objects. You can find out more about breakable constraints in Breakable Constraints (page 2–735).

**Display group**

**Size**—Lets you change the size of the constraint space display in the viewport.

**Reset Default Values**—Returns the constraint's parameters to their default values.

---

**Car-Wheel Constraint**

Create panel > Helpers > reactor > Carwheel

Menu bar > reactor > Create Object > Car-Wheel Constraint

reactor toolbar > Create Car-Wheel Constraint button

You can use this constraint to attach a wheel to another object; for instance, a car chassis. You can also constrain a wheel to a position in world space. During the simulation, the wheel object is free to rotate around a spin axis defined in each object’s space. Linear motion is allowed for the wheel along a suspension axis. You can also add limits to the wheel’s movement along this axis. The constraint’s child body always acts as the wheel, while the parent acts as the chassis.
The Car-Wheel constraint also has spin parameters. If these are nonzero, the constraint turns the wheel during the simulation. You can specify a target velocity and a target gain: the maximum angular impulse that the motor can apply to the rigid body in order to achieve the target velocity.

A Car-Wheel constraint is simulated if it has the correct number of rigid bodies attached and is included in a valid Constraint Solver (page 2–736). When not selected, an invalid Car-Wheel constraint is red in the viewport.

Procedures

To create a Car-Wheel constraint:

- Choose one of the above options, and then click in any viewport to add the Car-Wheel constraint.
  
  Note: The icon’s position has no effect on the constraint’s behavior.

To attach objects to the Car-Wheel constraint:

1. Create the constraint and the objects to connect using it.
2. On the constraint’s Properties rollout, click the Child pick button, and then, in one of the viewports, select the object you want to use as the wheel.

   This attaches the constraint to the wheel at the wheel’s pivot point. The spin axis is aligned to the X axis of the wheel object and the suspension axis is aligned to the Z axis.
3. If you do not want to assign a chassis to the Car-Wheel constraint, turn off the Parent check box if necessary.
4. If the Car-Wheel constraint is to be two-bodied, repeat step 2, using the Parent pick button to specify the chassis object for the constraint.
5. To reset the attachment point to the child’s pivot, reattach the objects to the car-wheel constraint or choose the Align Spaces To Child Body option.

To create the constraint and attach objects in a single step:

- See the Scripts (page 2–817) topic.

To change the positions and rotations for the bodies:

1. With the constraint selected, open the Modify panel.
2. In the modifier stack open the constraint’s sub-object list.
3. Access the sub-object level corresponding to the object whose constraint space you want to move: Parent Space for the chassis or Child Space for the wheel. If the constraint is single-bodied, Parent Space represents the world attachment position and rotation of the constraint axes.
4. The space, represented by just a spin axis for the wheel and by the spin and suspension axes for the chassis, becomes active in the viewport and can be moved or rotated using the Move or Rotate tool, respectively. The space maintains its position and rotation relative to its corresponding object. For example, if you move or rotate the wheel, Child Space moves with it.
6. You can also rotate the suspension axis independent of the spin axis. To do this, highlight the Suspension Rotation sub-object level; this lets you rotate the suspension axis with respect to the chassis's spin axis.

To change the suspension limits:
1. With the car-wheel constraint selected, open the Properties rollout.

The default limit settings in the Suspension Parameters group are Min Limit=0.0 and Max Limit=0.0. This means that in a situation where the constraint spaces are fully aligned for the objects, the wheel cannot move along the suspension axis.

The limits define the allowed motion of the wheel along the suspension axis with respect to the chassis, and are displayed as a line with respect to the chassis. This means that from a stable position where the sub-objects are aligned, if the limits are –5 and 10, the wheel will be able to move 10 units away from chassis along the suspension axis in the direction of the icon's arrow and 5 units in the opposite direction.

2. Change the limits and observe the difference in the simulation.

3. You can also change Friction for the Car-Wheel constraint; this inhibits the wheel's motion along the suspension axis.

To spin the wheel:
These controls are found in the Spin Parameters group.
1. Set the Velocity value to the required value. This is specified in radians per second.
2. Set the Gain. This is the maximum angular impulse the constraint can apply to maintain this angular velocity.

Parent Space—At this sub-object level, you can move and rotate the representations of spin and suspension axes for the chassis. This describes where on the chassis the wheel is attached and also the directions of the spin and suspension axes for the chassis. This is defined in chassis space, which means that if you alter the position or rotation of the chassis the axes will move as well and maintain their offset rotation and translation with respect to the chassis. When you assign a chassis to the car-wheel constraint, Chassis Space’s translation is set to the wheel’s pivot point, the spin axis is aligned to the wheel’s X axis, and the suspension axis is aligned to its Z axis. If the car-wheel constraint is single-bodied, then Chassis Space represents the world orientation and position of the constraint.

Child Space—At this sub-object level, you can move and rotate the representation of the constraint for the wheel. This describes both the location on the wheel that the constraint considers as its
attachment point and the rotation of the spin axis for the wheel. This is defined in wheel space, which means that if you alter the position or rotation of the wheel the space moves as well and maintains its offset rotation and translation with respect to the wheel. When you assign a wheel body to the Car-Wheel constraint, Wheel Space’s translation is set to the wheel’s pivot point and the wheel’s spin axis is aligned to its X axis.

**Suspension Rotation**—This level allows independent rotation of the suspension axis with respect to the Chassis Space. This means that your suspension axis doesn’t have to be perpendicular to your spin axis, allowing for a greater range of constraint setups.

Car-Wheel Constraint

**Parent**—When on, the constraint has two bodies and you can designate an object to be the optional chassis rigid body attached to the Car-Wheel constraint. When off, the constraint is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the chassis by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the chassis object.

**Child**—Displays the name of the second rigid body attached to the constraint. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

**Align Spaces To**—Use these options to align the bodies’ local constraint spaces. You can find out more about each option in *Working With Constraint Spaces* (page 2–726).

**Lock Relative Transform**—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves and rotates along with it, and vice-versa.

### Strength group

**Strength/Tau**—Govern the impulses applied to the constraint’s bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement. You can find out more about these parameters in *Strength and Tau* (page 2–735).

### Suspension Parameters group

**Min Limit**—The distance the constraint allows the wheel to move along the suspension axis relative to the chassis, in the direction opposite that indicated by the icon’s suspension arrow. For example, if Min Limit=−5, then the wheel cannot move more than five units backwards along the suspension axis with respect to the constraint’s spaces.

**Max Limit**—The distance the constraint allows the wheel to move along the suspension axis relative to the chassis, in the direction indicated by the icon’s suspension arrow. For example, if Max Limit=10 then with respect to the constraint’s spaces the wheel cannot move more than 10 units forward along the suspension axis.

**Friction**—The level of friction applied to the objects as they try to move relative to each other along the suspension axis. Available with Havok 1 only.

**Strength**—The strength value of the suspension spring. Higher values cause less vertical movement. Available with Havok 3 only.

**Damping**—The damping value of the suspension spring. Higher values suppress vertical oscillation. Available with Havok 3 only.

### Spin Parameters group

**Velocity**—This value indicates the angular velocity in radians per second that the constraint will seek to achieve for the wheel.

**Gain**—This value indicates the maximum angular impulse the constraint can apply to attain the specified angular velocity.

### Breakable group

**Breakable**—When on, the constraint is breakable. If its breakable limits are exceeded during simulation, it ceases to exert impulses on the attached objects. For more information, see *Breakable Constraints* (page 2–735).

### Display group

**Size**—Lets you change the size of the constraint space display in the viewport.

**Reset Default Values**—Returns the constraint’s parameters to their default values.
The Point-Path constraint allows you to constrain two bodies so that the child is free to move along a specified path relative to the parent. Alternatively, you can create a single-bodied version of the constraint, where the constrained body can move along a path in world space. The child body’s orientation is not restricted by the constraint.

You could, for example, use a Point-Path constraint to simulate a bead on a wire. In most cases, you don’t need to specify a parent rigid body for a Point-Path constraint, unless the motion of the path itself should follow another rigid body.

The constraint is simulated if it has the correct number of rigid bodies attached, a specified path shape, and is included in a valid Constraint Solver (page 2–736). When not selected, invalid constraints are red in the viewport.

Procedures

To create a Point-Path constraint:

1. Select one of the above options, and then click in any viewport to add the Point-Path constraint.

   Note: The icon’s position has no effect on the constraint’s behavior.

To specify objects and a path for the constraint:

1. Create the constraint and the bodies to constrain.

2. Create a line or curve in the viewport using one of the Shapes tools on the Create panel.

3. In the constraint’s Properties rollout, click the Child pick button, and then select the object you want to use as the child object in one of the viewports.

4. If you do not want to assign a second body to the constraint, turn off the Parent check box if necessary.

5. If the constraint is to be two-bodied, repeat step 2, using the Parent pick button to set the parent for the constraint.

6. Use the Path pick button to designate the path. The constraint icon moves to the designated path. By default, this constraint type is aligned so that the parent constraint space is aligned with the path shape’s local space, while the child space is aligned with the child body’s local space.

To change the path position and orientation for the bodies:

1. With the constraint selected, open the Modify panel.

2. In the modifier stack open the constraint’s sub-object list.

3. Access the sub-object level corresponding to the object whose constraint space you want to move: Child Space or Parent Space. If the Point-Path constraint is single-bodied, Parent Space represents the world position and rotation of the path.

4. The space, represented by a set of axes and the path, becomes active in the viewport and can be moved or rotated using the Move or Rotate tool, respectively. The space maintains its position and rotation relative to its corresponding object. For example, if you move or rotate the child body, Child Space moves with it.

**Parent Space**—At this sub-object level, you can move and rotate the representation of the constraint for the parent body. The axes and path are defined in the parent body’s space, which means that if you alter the position or rotation of the parent, the space moves as well and maintains its offset rotation and translation with respect to the parent. When you assign a parent body to the constraint, Parent Space is aligned with the path’s local space. If the constraint is single-bodied, then Parent Space represents the world orientation and position of the path.

**Child Space**—At this sub-object level, you can move and rotate the representation of the constraint for the child body. The axes and path are defined in the child body’s space, which means that if you alter the position or rotation of the child, the space moves as well and maintains its offset rotation and translation with respect to the child. When you assign a child body to the constraint, the Child Space is aligned with the child body’s local space.

Properties rollout

![Properties rollout](image)

**Parent**—When on, the constraint has two bodies and you can designate an object to be the parent body. When off, the constraint is single-bodied and the point occupied by the Parent Space sub-object is the parent.

You assign the parent object by clicking this button and then selecting a rigid body from any viewport. Thereafter the button displays the name of the parent body.
Child—Displays the name of the second rigid body attached to the constraint. You assign the child object by clicking this button and then selecting a rigid body from any viewport.

Align Spaces To—Use these options to align the bodies’ local constraint spaces. You can find out more about each option in Working With Constraint Spaces (page 2–726).

Lock Relative Transform—When on, the relative transform between the child and parent constraint spaces is locked: If you move either space in the viewport, the other space moves and rotates along with it, and vice-versa.

Strength group
Strength/Tau—Govern the impulses applied to the constraint’s bodies in order to maintain the constraint, and so how strongly the constraint works to restrict their movement. You can find out more about these parameters in Strength and Tau (page 2–735).

Breakable group
Breakable—When on, the constraint is breakable. If its breakable limits are exceeded during simulation, it ceases to exert impulses on the attached objects. You can find out more about breakable constraints in Breakable Constraints (page 2–735).

Display group
Size—Lets you change the size of the constraint space display in the viewport.
Reset Default Values—Returns the constraint’s parameters to their default values.

reactor Objects

Plane

Create panel > Helpers > reactor > Plane
Menu bar > reactor > Create Object > Plane
reactor toolbar > Create Plane button

The reactor Plane as rendered in a viewport

The reactor Plane object is a type of rigid body that acts as a fixed, infinite plane in the simulation. It shouldn’t be confused with the standard 3ds Max plane, which can also be used as a rigid body provided its simulation geometry property (page 2–719) is set to Concave Mesh.

Like other rigid bodies, the Plane can have display proxies assigned to it and can be contained in a compound rigid body. You can also assign friction and elasticity values to it. However, it is always fixed in the simulation (the Mass (page 2–718) and Unyielding (page 2–718) properties are ignored).

The reactor Plane acts in only one direction, as shown in the viewport by an arrow pointing away from its solid surface. This means that rigid bodies approaching the plane from the "wrong" direction pass through it. You can, of course, also use two opposing planes.
Procedures
To create a Plane:
1. Choose one of the above options, and then click in any viewport.
   The plane’s normal is aligned with the viewport’s Z axis.
2. Use the Move and Rotate tools to adjust its position and orientation, as necessary.

Interface
Properties rollout

Show Normal—When on, the Plane normal is displayed as an arrow in the viewport.

Motor
Create panel > Helpers > reactor > Motor
Menu bar > reactor > Create Object > Motor
reactor toolbar > Create Motor button

The Motor helper lets you apply a turning force to any non-fixed rigid body in the scene. You can specify the angular velocity for the target and the maximum angular impulse the Motor can apply to achieve this velocity.

You do not need to add a Motor explicitly to a simulation, as all valid motors in a scene are added to the simulation by default. A Motor is valid if its Rigid Body property has been set to a valid rigid body in the scene. When not selected, invalid motors are colored red in the viewport.
**Ang Speed**—The target angular velocity that the motor attempts to achieve for the rigid body. It is specified in radians per second, so the default value of 3.14 (pi) results in 180 degrees of rotation per second or half a revolution per second.

**Gain**—The maximum angular impulse that the motor can apply to the rigid body in order to achieve the target velocity.

**Rotation Axis**—The local axis for the rigid body about which the motor applies impulses. This axis has a visual representation when the motor helper is selected.

**Disabled**—When on, the motor is not added to the simulation.

**Size**—The size of the rotation axis in the viewport.

**Reset Default Values**—Returns Ang Speed, Gain, and Rotation Axis to their default values.

---

**Toy Car**

Create panel > Helpers > reactor > Toy Car

Menu bar > reactor > Create Object > Toy Car

reactor toolbar > Create Toy Car button

The reactor Toy Car is a quick way to create and simulate a simple car without having to set up each constraint separately.

The Toy Car helper lets you choose a chassis and wheels for your car, tweak various properties such as the strength of its suspension, and specify whether you would like reactor to turn its wheels during the simulation. reactor then sets up all the necessary constraints to simulate the car.

A Toy Car is simulated if it has a rigid body assigned as a chassis and at least one rigid body assigned as a wheel. When not selected, an invalid Toy Car helper is red in the viewport.

**Procedures**

To set up a toy car, follow these procedures in order, and make sure the car has a surface to travel on, such as a level plane. For getting started, we suggest you use Icon Orientation and ignore the procedure about Common Local Orientation.

**To create a Toy Car helper:**

- Choose one of the above menu options, and then click in any viewport to add the Toy Car.

Note: The icon’s initial position has no effect on the car’s behavior.

**To set up the rigid bodies for a Toy Car:**

1. Create and position the rigid bodies you want to connect using the Toy Car helper.

A toy car must have a chassis and at least one wheel.

2. Use the Rigid Body Properties dialog to assign a mass value to each car element.

The Mass values you specify affect how the toy car behaves. Ideally, the mass of the chassis should not be much greater than the total wheel mass, and the density of the bodies should be
such that the Analyze World utility generates no warnings.

To assign rigid bodies to a Toy Car:
1. Create the Toy Car helper and the objects to connect using it, as described above.
2. On the Properties rollout, click the Chassis pick button, and then, in one of the viewports, select the object to use as the chassis.
   The Toy Car icon moves to the chosen rigid body. By default, the icon is aligned with the chassis's local space. reactor can use this orientation as a guide for the directions of the suspension and wheel axes.
3. Add your car's wheels to the helper. You can add wheels to the toy car either by picking or using a selection list:
   - Click the Pick button and then select the object to use as a wheel.
   - Click the Add button and then use the dialog to select one or more objects to use as wheels.

By default, reactor uses the icon orientation (taken from the chassis) to provide the directions of the wheels' spin and suspension axes. Each spin axis is aligned with the icon's X axis and passes through the relevant wheel's pivot point. The suspension axes are aligned with the icon's Z axis, and also pass through each wheel's pivot point.

Note: For this to work, make sure that the wheels are oriented correctly relative to the icon before simulating.

To change the wheel axis orientation (Icon Orientation):
1. Use the Rotate tool to change the toy car icon's orientation so that it matches that of the actual car model.
2. Ensure that Toy Car Properties rollout > Toy Car Orientation is set to Icon Orientation (the default).
   The wheel axes are aligned with the icon's new orientation during the simulation.

To change the wheel axis orientation (Common Local Orientation):
1. Ensure that the wheel and chassis local spaces are correctly aligned in world space.
   The initial world space orientation of the wheels relative to the chassis/icon is unimportant when using this option, as reactor reorients the bodies so that their local spaces continue to match during the simulation.
2. On the Toy Car Properties rollout, set Toy Car Orientation to Common Local Orientation.
3. Use the radio buttons to change the Suspension and Spin directions relative to the bodies' local spaces. By default, the Spin axes are aligned with the wheel and chassis's local X axes, and the suspension axes with their Z axes.

To spin the Toy Car wheels:
1. On the Toy Car Properties rollout, turn on the Spin Wheels check box.
2. Change the default Ang (Angular) Speed and Gain values as necessary.
   Angular Speed is the target angular velocity that reactor attempts to achieve for the wheels. The Gain is the maximum angular impulse that can be applied to the wheels in order to achieve the target velocity.
Interface

Toy Car Properties rollout

**Chassis**—Displays the name of the rigid body that serves as the chassis. You assign the chassis object by clicking this button and then selecting a rigid body from any viewport.

**Wheels**—Lists the names of the toy car’s wheels.

**Pick**—Lets you add a wheel to the car. Click this button, and then in the viewport position the cursor over the object you would like to use as a wheel. If the object can be used as a rigid body, the cursor changes from an arrow to a cross and you can select the object to add it to the toy car.

**Add**—Lets you add one or more rigid bodies from the scene to act as wheels for the toy car. Click the button to open the Select Car Wheels dialog. Make a selection in the provided list, then add the wheels to the car by clicking the Select button.

**Delete**—Lets you remove wheels from the car. Highlight the wheels to remove from the car in the Wheels list and then click this button.

Note: The following four parameters are available with Havok 1 only. With Havok 3, use the Havok 3 Wheel Params rollout (page 2–769) settings instead.

**Angular Strength**—The strength of the corrective forces applied to keep the wheels upright and pointing forward.

**Linear Strength**—The strength of the forces applied to keep the wheels in position relative to the chassis.

**Suspension**—The suspension strength for the car. The lower the value, the more the chassis bounces when forces are applied to it.

**Internal Substeps**—Allows the car to be simulated using more substeps per keyframe than the rest of the simulation.

Increasing the Internal Substeps value can be useful if you are simulating a car with unusual parameters, which might require more substeps for stability.

**Toy Car Orientation group**

Choose how reactor orients the bodies in relation to the spin and suspension axes.
**Icon Orientation**—The Toy Car icon’s initial orientation provides the directions of the wheels’ spin and suspension axes. Each spin axis is aligned with the icon’s X axis and pass through the relevant wheel’s pivot point. The suspension axes are aligned with the icon’s Z axis, and also pass through each wheel’s pivot point. The wheels’ own local orientations are unimportant.

Note: Animating the orientation of the Toy Car icon has no effect on the direction of motion during the simulation; reactor uses only the orientation at the start of the simulation.

**Common Local Orientation**—With this option, you align the bodies’ local spaces in world space, and specify the Spin and Suspension axes relative to this common orientation. The orientation of the rigid bodies in world space before simulating is unimportant.

This means, for instance, that you can set up your car with its wheels turned sideways and they still spin around the correct axes when simulating. This option allows you to change the spin and suspension axes separately. By default, the spin axes are aligned with the wheel and chassis’ local X axes, and the suspension axes with their Z axes.

**Allow Wheel Penetration**—When on, reactor disables collision detection between the chassis and the wheels.

**Spin Wheels**—When on, the car’s wheels to spin during the simulation and an arrow appears on the Toy Car viewport icon showing the direction of motion.

* **Ang Speed**—The target angular velocity that reactor attempts to achieve for the wheels when Spin Wheels is on. It is specified in radians per second, so the default value of 3.14 (pi) results in 180 degrees of rotation per second or half a revolution per second.

* **Gain**—The maximum angular impulse that reactor can apply to the wheels in order to achieve the target velocity.

**Disabled**—When on, reactor removes the Toy Car helper from the simulation.

**Display Size**—The size of the Toy Car helper icon as displayed in the viewport.

**Reset Default Values**—Returns the Toy Car parameters to their default values.

**Havok 3 Wheel Params rollout**

These parameters apply only when the simulation engine is Havok 3, and reflect the implementation of a subset of Car-Wheel constraint parameters in the Toy Car object in Havok 3.

These parameters replicate the Car-Wheel constraint parameters of the same names (page 2–761).
Chapter 13: reactor

The Fracture helper object simulates the breaking of a rigid body into a number of smaller pieces as the result of an impact. To do this, you need to supply the pieces that are glued together to create the whole object. This is known as "pre-fracturing." reactor does not break the pieces you supply into smaller pieces.

Tip: An excellent tool for pre-fracturing your objects is the ProCutter compound object (page 1–388).

Rigid bodies that are part of a Fracture helper move together as a single body. When a rigid body that belongs to a Fracture helper collides with another body, the collision information is analyzed and if a threshold is exceeded, the rigid body is removed from the fracture helper. Once the rigid body has been removed, it moves independently of the fracture object and is free to collide with the rigid bodies that are still part of the fracture object. This can often result in a chain reaction of pieces breaking off.

You can optionally enable the use of connectivity. Connectivity analyzes the bodies belonging to the Fracture helper to find bodies that are in contact with each other before simulation occurs. This builds up an internal graph of which bodies are connected to which other bodies. Thus groups of rigid bodies that are connected to each other, but disconnected with other bodies in the fracture helper, can move independently as separate fracturable objects. As a result, you can get the effect of multiple fracturable objects in a single Fracture helper.

After a fracture event occurs, reactor once again analyzes this connectivity graph to create new chunks if they exist. If you see floating disconnected bodies moving strangely because they are invisibly still part of a larger fracture object, be sure to turn on connectivity. A body is considered to be in contact with another body if the closest distance between them is less than the collision tolerance.

To allow the fracture feature to work reasonably well, reactor uses a special collision detection technique: penetration depth calculation. Unlike normal rigid bodies in reactor, bodies that are part of a fracture helper are allowed to continue to collide with each other, even when they are in a interpenetrating state. To see how the non-fracture bodies are treated during collision detection, see the Fracture Tips (page 2–773) topic. Penetration depth calculation, especially in the context of the simulation paradigm used in reactor, is computationally expensive, so you might notice slower performance when the fracture bodies are penetrating each other. Stability in these cases can also become an issue.

reactor provides a number of techniques for getting your fracture simulation to behave more realistically. If you find that it is unstable. For instance, the fractured object might appear to
explore after a single piece breaks loose. You can find these in the Fracture Tips (page 2–773) topic.

**Procedures**

**To create a Fracture helper:**
- Choose one of the above menu options, and then click in any viewport to add the Fracture helper.

  **Note:** The icon’s position has no effect on the fracture object’s behavior.

**To add rigid bodies to a Fracture helper:**
1. Create a Fracture helper in the scene and some objects to use as rigid bodies.
   You can add rigid bodies to the helper in two ways: by picking or by using a selection list.
2. With the Fracture helper selected, use either (or both) of the following methods:
   - Click the Pick button on the Properties rollout and then select the rigid body to add to the helper.
   - Click the Add button and then use the dialog to select one or more objects to use as fracture elements.

   The names of rigid bodies you add appear in the helper’s Pieces list.

**To create the Fracture helper and add objects in a single step:**
- See the Scripts (page 2–817) topic.

**To prevent the Fracture object from exploding:**
- See the Fracture Tips (page 2–773) topic.

**Interface**

Properties rollout

---

**Highlight**—Click this button to cause the objects in the Pieces list to momentarily display as if selected.

**Pieces**—Lists the names of the objects currently part of the Fracture object. To highlight multiple contiguous list items, click and then Shift-click.
To highlight multiple non-contiguous list items or remove highlighting, use [Ctrl]-click.

**Pick**—Lets you add an object to the Fracture helper. Click this button, and then in the viewport position the cursor over the object to add to the helper. If the object can be used as a fracture piece, the cursor changes from an arrow to a cross and you can select the object to add it to the helper.

**Add**—Lets you add one or more objects from the scene to the helper. Click the button to open the Select Rigid Bodies For Fracture dialog. Make a selection in the provided list, and then press the Select button to add the objects to the helper.

**Delete**—Lets you remove objects from the helper. In the Pieces list, highlight the bodies to remove from the helper and then click this button.

---

**Selected piece**

You can assign these properties to pieces highlighted in the Pieces list.

**Broken**—This read-only check box shows whether any of the highlighted pieces have broken off at the current frame. For example, say you’ve created an animation from frame 0 to frame 50 using Fracture, where piece A broke off at frame 10. Highlighting piece A and moving the time slider to frame 10 or after automatically turns on Broken. Moving the time slider to frame 9 or before turns off Broken. This is because reactor keeps track of the times pieces break off. That way, if you continue the animation at frame 50, reactor knows it shouldn’t add piece A to the fracture object, so it keeps moving independently. You can restore a highlighted piece to its "unbroken" state with the Reset button (see following).

**Reset**—This button is available if any of the pieces broke off during a previous animation (reactor stores the times when pieces broke off). Clicking this button tells reactor to ignore the times they broke off in the previous animation.

Choose the behavior for highlighted pieces:

- **Normal**—The default behavior option for a fracture piece.
- **Unbreakable**—The highlighted piece never breaks away from the Fracture object, even if it experiences an intense collision.
- **Keystone**—If this piece breaks, then all pieces break.
- **Break At Time**—The selected piece breaks at the time you specify. For this kind of piece the Broken check box reflects the state of the piece at the current frame. Thus, if you set a piece to break at frame 5, the Broken check box is on at frame 5 and later, and off at frames before 5.

**Use Connectivity**—When on, groups of pieces that are connected to each other move independently of pieces that they are not connected to. This is like having multiple fracture objects contained in one fracture helper. The collision detector determines that two pieces are connected to each other if their distance from each other is less than the world’s **Collision Tolerance**.

**Break on**

Choose the method by which reactor determines whether fracturing should occur:

- **Impulse**—When a piece of the fracture object experiences a collision where the impulse is greater than the threshold specified, it breaks off from the fracture object. The impulse of the collision is proportional to both the relative velocity of the collision and the mass of the objects involved in the collision. The higher the mass of the object that hit the piece, the larger the impulse.
- **Velocity**—When a piece of the fracture object experiences a collision where the relative velocity is greater than the threshold specified,
it breaks off from the fracture object. The size or mass of the object is not be taken into account.

**Energy Loss**—The amount of extra kinetic energy is lost in the collision due to the breaking of the fracture bonds. This has the effect of dampening the collision somewhat and also transferring energy to the remaining, unbroken pieces of the fracture object. To simulate a brittle object, with maximum shatter effect, keep this value low. To simulate breakage of a material more like wood or concrete, use a high Energy Loss value.

Tip: Increasing this value can improve the performance and stability of the simulation.

**Display: Show Bounding Box** — When on, the viewports display a box that contains all the pieces of the fracture object.

**Disabled** — When on, the Fracture helper has no influence on the rigid bodies that are part of it.

**Reset Default Values**—Returns the settings to their default values.

World rollout > Fracture Penetrations group

Several additional values govern fracture behavior. These are global in that they apply to every rigid body added to a Fracture object, and are found in the Utility panel > reactor > World rollout.

These values control the behavior of penetration depth collision detection and response, and apply only to objects that are included in a Fracture helper.

<table>
<thead>
<tr>
<th>Fracture Penetrations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Separation Time</td>
</tr>
<tr>
<td>Velocity Cap</td>
</tr>
<tr>
<td>Scale Tolerance</td>
</tr>
</tbody>
</table>

**Separation Time**—Forces are applied to penetrating bodies that are strong enough so the bodies become separated within the time specified. To simulate an explosion effect, make this value very small and reduce the Velocity Cap value.

**Velocity Cap**—reactor won’t apply penetration recovery forces if they cause the relative velocity between two penetrating bodies to exceed the specified value.

**Scale Tolerance**—The collision tolerance for bodies that use the penetration depth algorithm is determined by multiplying the Collision Tolerance value by the value specified. If this value is negative, the collision tolerance will extend inside the bodies, effectively shrinking the collision geometry.

For more information about using these values, see the Fracture Tips (page 2–773) topic.

---

**Fracture Tips**

After you procedurally slice up an object for fracture, the new pieces fit snugly among each other. When one piece breaks loose after a fracture event, it might be in contact with other pieces that are still part of the non-fractured body. This can throw the broken piece into unstable oscillations against two or more opposing pieces. The result is a chain-reaction throughout the fracture body, with all the pieces flying off into space. It might appear as though some of the pieces simply wink out of existence. Unlike normal rigid bodies in reactor, Fracture pieces are allowed to exist in a state of interpenetration, where restoring forces are applied to separate them. Many objects sitting in penetrating states next to each other can result in an unstable system.

**To make the system more stable and less prone to exploding:**

Try one or more of the following:

- Reduce the Scale Tolerance value in the Fracture Penetrations group of the reactor utility World rollout.

---
This value can be as low as –1.0, but –0.1 should suffice in most cases. This scales the Collision Tolerance (page 2–808) for pieces of a fracture object. A negative Scale Tolerance value effectively shrinks the object as it is perceived by the collision-detection system. Pieces that were snug against each other now have a comfortable safety zone where no collisions take place. This is tied to the Collision Tolerance value, so changing Collision Tolerance changes the effective tolerance used when fracture pieces collide with other fracture pieces. It dramatically reduces unstable oscillations. This is the most effective thing to try when you wish to avoid explosions.

- Manually offset the pieces from each other, leaving a physical gap between all pieces. The gap should be as big as Collision Tolerance * Scale Tolerance.
- Increase the Energy Loss value on the Fracture object’s Properties rollout. This is the percent of energy that can be “lost” in the fracture event by transferring momentum from the broken piece to the unbroken Fracture object. Increasing it increases the relative velocity between the newly fractured piece and the remaining unfractured pieces. Ultimately this reduces the chances of a chain-reaction of unstable oscillations.
- Increase the Separation Time value and/or decrease the Velocity Cap in the Fracture Penetrations (page 2–773) group of the World rollout. This controls how aggressively reactor pushes the pieces out of a state of interpenetration. After doing this you may notice visible interpenetrations.
- Slice up your object in a different configuration. Avoid creating very small pieces, especially if they are right next to very large pieces.
- Turn on the Use Connectivity check box on the Properties rollout of the Fracture helper. When connectivity is enabled, clumps of pieces that are disconnected from other clumps but still internally glued to each other are set free to move independent of the other clumps. This serves to create gaps between fractured pieces earlier, so unstable oscillations won’t happen.

### Storing and Accessing Collisions

reactor lets you store information about all rigid body collisions that occur during the simulation. You can access this information via MAXScript or save it to a text file. The information includes the objects involved, the point of collision, and the relative velocity during collision. You can then use it to generate particles or other effects in your animation when objects collide, trigger sounds, and so on.

You can activate and configure collision storing using the reactor utility’s Collisions rollout (page 2–810).

#### Interface

**Store Collisions group**

- **Do not store**
- **Store once**
- **Always store**

14 collisions stored

- **View**
- **Clear**

**Filter before storing**

- **Objects...**
- **Velocity > 0.2m**
**Store Collisions**—Use these options to store collision information when creating an animation. For each collision that occurs during the simulation, reactor can record the simulation time at which the collision occurred, the objects involved, the point of collision, and the relative velocity during the collision.

- **Do not store**—reactor stores no collision data.
- **Store once**—reactor stores collision data next time an animation is created.
- **Always store**—reactor always stores collision data when creating an animation.

**# collisions stored**—This read-only field reports how many collisions were stored in reactor last time an animation was created.

**View**—Opens the **Stored Collisions dialog (page 2–775)**, which shows all the currently stored collision information.

**Clear**—Deletes all stored collision information.

### Filter Before Storing

These options let you provide more specific details about the collision information you want to record.

**Objects**—When on, lets you store only collisions involving particular objects. Use the Objects button to designate those objects.

Click this button to open the **Filter Bodies In Collisions dialog (page 2–776)**. This allows you to select the pairs of objects whose collisions interest you. Only collisions involving those pairs of objects are stored.

**Velocity**—When on, reactor stores only collisions that occur above a certain velocity. You can specify the threshold velocity using the provided field. reactor ignores this filter for **phantom collisions**.

**Define Collision Pairs**—Allows you to enable or disable collision detection between specified pairs of objects. You can find out more about this in the **Collisions Rollout (page 2–810)** topic.

### Stored Collisions Dialog

**Collisions List Box**—This list box shows all the information stored about the collisions occurred during the last animation. The information is organized in different columns:

- **Ticks**—The time, in ticks (1/4800th of a second) when the collision happened.
- **Frame / SMPTE / MM:SS:Ticks**—The time, in the current time units (which can be frames, ticks, SMPTE, etc.), when the collision happened.
- **Object A**—The first rigid body involved in the collision.
- **Object B**—The second rigid body involved in the collision.
- **Point**—The location of the collision, in world coordinates.
- **Normal**—The unit normal of the collision, specified from B to A.
- **Speed**—The relative velocity of the two objects along the specified normal direction.
- **Phantom**—Specific information generated by **phantom rigid bodies**. There are three possible values:
  - **Not Phantom**—This collision wasn’t generated by a phantom rigid body.
  - **Entering**—The time the phantom rigid body started penetrating (entered) the other rigid body.
Leaving—The time the phantom rigid body finished penetrating (exited) the other rigid body.

Close—Closes the dialog.

Save—Allows you to save the stored information in a text file. This is an example of the format:

```
Time : 4175
A : Box01
B : Teapot01
Point : ( 3.25862 -56.7632 10.0549 )
Normal : ( 1.28512e-007 3.18186e-007 -1 )
NRV : 53.4184
Phantom : Not Phantom
Time : 4415
A : Phantom
B : Box01
Point : ( 0 0 0 )
Normal : ( 0 0 0 )
NRV : 0
Phantom : Not Phantom
```

Filter Bodies In Collisions dialog

**Bodies**—Lists the names of the reactor bodies in the scene. Highlighting an object populates the Store Collisions and Do Not Store Collisions lists for that object with respect to the other bodies in the scene. If you highlight more than one object in this list, how the lists are populated depends on the value of Common Collisions.

**Common Collisions**—When on, if more than one rigid body is highlighted in the Bodies list, the Store and Do Not Store lists are populated from the list of possible pairs that can be made using only your selected objects. When off, the lists contain all possible pairs from the scene that contain at least one of your selected objects.

For example, take a scene containing four rigid bodies: Box01, Box02, Box03 and Box04. If Common Collisions is on, and you highlight Box01 and Box02 in the Bodies list, then the only possible pair that includes only your selected objects is Box01<->Box02.

If you highlight Box01, Box02, and Box03, then the possible pairs using these objects are Box01<->Box02, Box02<->Box03, and Box01<->Box03. If highlight the same objects with Common Collisions off, then the lists also include the highlighted objects paired with the remaining objects in the collection. This means that the available pairs would also now include Box01<->Box04, Box02<->Box04 and Box03<->Box04.

This option is selected by default.

**Store Collisions**—Collision data is stored for any pairs of objects in this list.

**Do Not Store Collisions**—Collision data is not stored for these pairs of objects.

>`—Moves the pairs that are highlighted in the Store list to the Do Not Store list.

>>—Moves all the pairs in the Store list to the Do Not Store list.

<—Moves the pairs that are highlighted in the Do Not Store list to the Store list.
Deformable Bodies

You can use rigid bodies (page 2–716) in reactor to model any real-world object whose shape doesn’t change over time. However, what if you want to simulate an object whose geometry does change over the course of the simulation, such as a cloak, hair, foam bricks, or perhaps a slithering tentacle? reactor allows you to model these with a second category of objects, called deformable bodies.

The geometry (vertices) of deformable bodies can change over time, driven either by reactor during the simulation or by existing animation in 3ds Max, allowing the objects to bend, flex, and stretch while affecting and being affected by the rest of objects in the world simulation.

Important: The Havok 3 engine does not support deformable bodies in reactor; you can use these only with the Havok 1 engine.

In addition to creating entirely deformable objects, you can combine deformable bodies with rigid bodies, for instance to add secondary motion to a simulated character. Secondary motion could include swirling clothing, wobbling flesh, or a swinging tail. Deformable objects are also useful for environmental effects such as swinging ropes and chains, curtains, and flags with dynamic wind.

Generally, you create a deformable body in reactor by first creating a mesh or spline that models the object’s basic shape, and then applying a special modifier. You can then specify additional physical properties for the object. reactor includes four main types of deformable bodies, each of which is dealt with in its own section:

- Cloth (page 2–778), a deformable two-dimensional triangular mesh
- Soft Body (page 2–783), a deformable three-dimensional closed triangular mesh
- Rope (page 2–789), a deformable one-dimensional chain of vertices.
- Deforming Mesh (page 2–793), a deformable mesh whose vertices have already been animated, for instance the skin on a character rig.

As with rigid bodies, you must add deformable bodies to a collection in order to be added to the simulation. Each deformable body type has its own corresponding collection type.

Also like rigid bodies, you can constrain the possible movement of deformable bodies: see Constraining Deformable Bodies (page 2–795).

Note: Deformable bodies are more complex than rigid bodies (page 2–716), so reactor requires more time to simulate them.

Working with Deformable-Body Vertices

reactor includes several tools for working with individual vertices in deformable bodies. The topics covering these are:

- Fixing Vertices in World Space (page 2–796)
- Keyframing Vertices (page 2–797)
- Attaching Vertices to a Rigid Body (page 2–798)
- Attaching Vertices to Deforming Meshes (Skin) (page 2–799)
- Soft Selection (page 2–800)
Cloth objects in reactor are two-dimensional deformable bodies. Using cloth objects you can simulate flags, curtains, clothing (skirts, capes, shirts), banners and even materials like paper and sheet metal.

This section contains two topics:

- **Cloth Modifier (page 2–778)**: Apply it to each mesh to be deformed as cloth.
- **Cloth Collection (page 2–781)**: A container for cloth objects.

### Cloth Modifier

The Cloth modifier lets you turn any geometry into a deformable mesh, allowing you to simulate the behavior of objects such as curtains, clothes, metal sheets, and flags. You can specify a number of special properties for cloth objects, including stiffness and how the object folds.

To add a cloth object to the simulation, you need to add it to a Cloth Collection (page 2–781).

### Procedures

**To create a Cloth object:**

1. Create the mesh object that you would like to simulate as cloth.

   **Note:** In reactor, the underlying topology of this object can influence the cloth’s behavior. For instance, cloth tends to fold along contiguous edges; highly tessellated meshes also stretch more, etc. Irregular triangulations (for example, a Delaunay triangulation of a 3ds Max NURBS surface) results in isotropic behavior (same behavior across all directions), avoiding artificial creases and folds around specific directions; it can therefore produce more realistic-looking results for pieces of clothing. Regular triangulations (like that of a standard 3ds Max plane) lead to anisotropic behavior (tendency to folding and creasing is different depending on the direction), this of course might be irrelevant or even desirable in some situations.

   **Tip:** A quick, easy way to create a Delaunay mesh for reactor Cloth is to apply the Garment Maker modifier (page 1–607) to a shape.
2. With the object selected, choose one of the above options.
   The Cloth modifier appears in the object’s modifier stack.

To edit a cloth object’s physical properties:
1. Select the appropriate object in the scene.
2. On the Modify panel, ensure that the reactor Cloth modifier is highlighted in the modifier stack.
3. Use the Properties rollout to edit the properties, which are described in the Interface section, following.

Interface
Modifier Stack

  - 101 keyframes stored
  - Clear Keyframes
  - Use Soft Selection

Reset Default Values
**Mass**—The Cloth object’s mass in kilograms. This affects the behavior during collisions with other objects, and also the stretching caused by attached rigid bodies (page 2–798): the higher the mass of the cloth, the less stretching induced by the rigid body.

**Friction**—The coefficient of friction for the cloth’s surface. As with rigid bodies, this affects how smoothly the cloth moves relative to surfaces it contacts. The Friction values for both objects in contact combine to produce a coefficient for the interaction.

**Rel Density**—Cloth has no volume, so reactor cannot calculate its density. Instead, reactor provides a buoyancy property for Cloth objects, which reflects its relative density. The default value is 1.0, the density of water. This value is important only if you are going to float or immerse the cloth in water.

**Air Resistance**—The extent to which the cloth loses energy as it moves.

**Force Model**—Choose the way forces in the simulation affect your cloth object:

- **Simple Force Model**—This default method is suitable for most situations.
- **Stiffness**—The stiffness of the cloth.
- **Damping**—How quickly the cloth dissipates energy as it changes shape.
- **Complex Force Model**—This more-accurate model of cloth dynamics is more computationally expensive to simulate. It provides parameters to specify the shear and stretch stiffness separately, as well as a physically accurate out-of-plane bend property.
  - **Stretch**—The cloth resistance to stretching.
  - **Bend**—The cloth resistance to bending.
  - **Shear**—The cloth resistance to shearing.
- **Damping**—How quickly the cloth dissipates energy as it changes shape.

**Fold Stiffness**—Fold stiffness governs the cloth resistance to folding.

- **None**—By default, Cloth objects have no fold stiffness, and behave like a loose material such as silk.
- **Uniform Model**—This model adds fold stiffness uniformly across the surface of the cloth, regardless of its topology.
- **Stiffness**—The fold stiffness value.
- **Spatial Model**—This more-complex model of fold stiffness can be useful if you are simulating a complicated piece of cloth, such as a dress. It allows you, for instance, to add fold stiffness only to sections of the cloth that are flat.
  - **Stiffness**—The fold stiffness value.
  - **Distance**—The degree of fold stiffness per unit area. A Distance value of 2 refers to twice the average triangle edge length in the cloth, so a large Distance value results in a large concentration of fold stiffness per unit area.
  - **Spread Angle**—Controls the degree to which fold stiffness is added to cloth when it has a non-flat shape. The angle relates to the threshold angle between two parts of the cloth, below which stiffness is added. If this value is 0.0, fold stiffness is added only to flat parts of the cloth.
  - **Split Angle**—The degree to which fold stiffness is added; specifically, how fold stiffness is concentrated along the grid lines of the cloth’s original mesh.

**Avoid Self-Intersections**—When on, the cloth will not intersect with itself during the simulation. This results in a more realistic-looking simulation, but can increase simulation time.
Constrain Deformation—When on, limits the extent to which the cloth can stretch.

- Max—A percentage value that indicates how stretchy the cloth is: The lower the value, the less stretching reactor allows.

Start With Current State—When on, the Cloth object starts the simulation using the current state stored in the modifier. This can be useful if you have, for example, draped the cloth around something in the Preview Window and then updated the viewport using Update MAX. When off, the cloth starts with the state it had originally, below the modifier. Available only when keyframes are stored.

# Keyframes Stored —This read-only shows the number of keyframes, if any, stored for the Cloth object. reactor stores keyframes for the object if you create a reactor animation, or if you use Update MAX in the Preview Window.

Clear Keyframes—Deletes any stored keyframes for the Cloth object.

Use Soft Selection—Allows you to use soft selection to smooth the transition between keyframed and simulated vertices for this deformable object. For more information, see Soft Selection (page 2–800).

Reset Default Values—Resets the values for the Cloth object to their defaults.

Constraints rollout

These options allow you to create different types of deformable constraints for the body. For more information, see Constraining Deformable Bodies (page 2–795).

Cloth Collection

The Cloth Collection is a reactor helper object that acts as a container for Cloth objects. Once you have added a Cloth Collection to your scene, you can add Cloth objects (object with a Cloth modifier (page 2–778)) in the scene to the collection.

When you run the simulation, reactor examines the cloth collections in the scene, and, provided
that the collections are not disabled, adds the cloth objects they contain to the simulation.

**Procedures**

**To create and use a Cloth Collection:**

1. Create some Cloth objects by applying the reactor Cloth modifier to standard objects.
2. Choose one of the above commands, and then click in any viewport to add the Cloth Collection.
   
   **Note:** The icon’s position has no effect on the collection’s behavior.

   The collection icon is added to the scene. You can add Cloth objects to the collection in two ways: by picking or by using a selection list.
3. Add objects to the collection using either (or both) of these methods:
   - On the Properties rollout, click the Pick button, and then in the viewport click an object to add.
   - On the Properties rollout, click the Add button, and then use the Select Cloths dialog to specify one or more objects to add.

**To create the collection and add objects in a single step:**

- See the *Scripts (page 2–817)* topic.

**Interface**

**Cloth Collection Properties rollout**

- **Highlight**—Causes the objects in the collection to flash momentarily in the viewports.
- **Cloth Entities**—Lists the names of the objects currently in the Cloth Collection.
- **Pick**—Adds an object to the cloth collection. Click this button, then in the viewport move the cursor over an object to add to the collection. If it is a Cloth object, the cursor changes from an arrow to a cross and you can select the object to add it to the collection.
- **Add**—Adds one or more objects from the scene to the collection. Click the button to open the Select Cloths dialog. Highlight one or more entries in the list, and then click the Select button to add the objects to the collection.
- **Delete**—Removes objects from the collection. In the Cloth Entities list, highlight the bodies to remove from the collection and click this button.
- **Disabled**—When on, the collection and the bodies it contains are not added to the simulation.
Advanced rollout

**Internal Steps**—Because deformable objects are more complex to simulate, it is usually necessary to perform more simulation steps (page 2–709) to increase stability. This parameter specifies the number of steps reactor performs internally to simulate objects in this collection for each simulation substep taken globally during the simulation. For example, at 60 fps, simulating at one keyframe (step) per frame, 10 substeps, at three internal substeps for this collection, reactor simulates the objects in this collection using $60 \times 10 \times 3 = 1,800$ steps per second, while the simulation in general uses $60 \times 10 = 600$ steps every second. This allows the objects in this collection to be simulated more accurately without slowing down the rest of the simulation. In general terms, you can think of it in this way:

- Precision (stability) of overall simulation = Number of Substeps (as specified on the Preview and Animation rollout (page 2–806))
- Precision (stability) of objects in this collection = (Precision of overall simulation) \times (Internal Substeps)

**Reset Default Values**—Restores Internal Steps to its default value.

---

**Soft Bodies**

Soft bodies are three-dimensional deformable bodies (page 2–777). Like Cloth (page 2–778) objects, they modify meshes. The main difference between cloth as soft bodies is that soft bodies have a notion of shape: a soft body tries, to some extent, to keep its original shape.

You can use soft bodies to simulate squishy objects like a partially deflated beach ball, a water bottle, jelly, or fruit. They are also useful for adding realistic secondary motion to your objects and characters: floppy ears, noses, tails, etc.

reactor provides two methods for simulating soft bodies:

- The mesh-based method uses the vertices in the mesh to operate (as with cloth and rope).
- **FFD soft bodies (page 2–786)** manipulate the control points in an FFD grid instead.

Depending on the complexity of your objects and the desired effect, you can use either method. The following sections go into more detail about them.

- **Soft Body Modifier (page 2–784)**: Apply it to each mesh to be deformed as soft body.
- **FFD-based soft bodies (page 2–786)**: Soft bodies deformed by an FFD modifier.
Chapter 13: reactor

- Soft Body Collection (page 2–788): A container for soft bodies.

Soft Body Modifier

Modify panel > Modifier List > reactor SoftBody
Menu bar > reactor > Apply Modifier > Soft Body Modifier
reactor toolbar > Apply Soft Body Modifier button

The Soft Body modifier lets you turn a rigid body into a closed, deformable, 3D triangular mesh, thus creating objects that can be flexed, bent, and squashed during the simulation. You can specify physical properties for soft bodies, including stiffness, mass, and friction.

reactor provides two types of soft body: mesh-based soft bodies, where reactor deforms the underlying mesh directly; and Freeform Deformation (FFD) bodies, in which reactor encases the original mesh in a simpler lattice that it uses to update the mesh. For more information about creating FFD bodies, see FFD Soft Bodies (page 2–786).

To add a soft body to the simulation, you need to add it to a Soft Body Collection (page 2–788).

Procedures

To create a soft body:

1. Create the mesh to use as the basic, non-deformed state of your soft body. You can turn any mesh with a fixed number of vertices into a soft body.

2. With the object selected, choose one of the above commands.

   The reactor SoftBody modifier appears in the object’s modifier stack.

To edit a soft body’s physical properties:

1. Select an appropriate object in the scene.

2. On the Modify panel, ensure that the reactor SoftBody modifier is highlighted in the modifier stack.

3. Use the Properties rollout to edit the properties, which are described in the Interface section, following.

Interface

Modifier Stack

Vertex—Allows you to select individual vertices of the soft body to which to apply and modify deformable constraints (page 2–795).
Soft Body Modifier

Soft Body Properties rollout

- Mass—The mass of the soft body in kilograms. This affects the soft body behavior upon colliding with other objects, its buoyancy when interacting with water, and the stretching caused by attached rigid bodies (page 2–798): the higher the mass of the soft body, the less stretch induced by the rigid body.

- Stiffness—The stiffness of the soft body: the stiffer it is, the harder it is to deform.

- Damping—The damping coefficient for the oscillation of the soft body’s compression and expansion.

- Friction—The coefficient of friction for the soft body’s surface. As with rigid bodies, this affects how smoothly the soft body will move relative to surfaces it’s in contact with. The friction values for both objects are combined to produce a coefficient for the interaction.

- Avoid Self-Intersections—When on, the soft body does not intersect with itself during the simulation. This results in a more realistic simulation, but can increase simulation time.

- [soft body type]—
  - Mesh-Based—By default, soft bodies are mesh-based - the modifier directly modifies the underlying mesh. This option is suitable for most simple objects, such as balls and bricks. For more complex meshes (greater than 200 triangles), however, this approach can be time-consuming and may slow down the simulation. A good alternative is to use FFD soft bodies (page 2–786).
  - # keyframes stored—This indicates the number of keyframes stored for the soft body, if any. reactor stores keyframes for the object if you create a reactor animation, or use Update MAX in the Preview Window.
  - Clear Keyframes—Clears any stored keyframes for this soft body.
  - Start With Current State—The soft body starts the simulation using the current state stored in the modifier. This can be useful if you have, for example, deformed the soft body in the Preview Window and then updated the viewport using Update MAX. When off, the soft body will start with the state it had originally (below the modifier).
  - Use Soft Selection—Allows you to use soft selection to smooth the transition between keyframed and simulated vertices for this deformable object. For more information, see Soft Selection (page 2–800).
  - FFD-Based—Uses the FFD version of the Soft Body modifier. For more information about
FFD bodies, including descriptions of these parameters, see FFD Soft Bodies (page 2–786).

**Reset Default Values**—Restores the default values for parameters in the modifier.

**Constraints rollout**

These options let you create different types of deformable constraint for the body. For more information, see Constraining Deformable Bodies (page 2–795).

reactor provides two different types of soft body: mesh-based soft bodies, where the underlying mesh is directly deformed, and Freeform Deformation (FFD) bodies. With an FFD body, reactor encases the original shape in a simpler FFD lattice. Then the simulation uses the lattice, rather than the object itself, as the soft body’s shape. As the lattice deforms, it updates the original shape so that it, too, appears to deform.

FFD bodies are less accurately modeled than mesh-based soft bodies, but also less computationally expensive to simulate. Because of this, it’s generally advisable to use an FFD-based soft body when deforming a complex mesh. As a general rule of thumb, if a mesh has more than 200 triangles, it’s probably a good idea to use an FFD-based soft body.

Note: When you view an FFD soft body in the Preview Window, you will see the FFD rather than the underlying shape. This should still give you some idea as to how the body will behave in your final animation.
Procedures

To create an FFD soft body:

1. Create the mesh to use as the basic, non-deformed state of your soft body.

2. Apply an FFD modifier: the FFD 2x2x2, 3x3x3, 4x4x4 (page 1–683) or FFD(box) (page 1–685) modifier.

   Different FFD dimensions produce different behavior. When using FFD(box), set the dimensions to a number that leaves the FFD vertices evenly distributed over the lattice. You can also use the Conform To Shape command to make the FFD lattice better represent the underlying geometry.

3. Apply the reactor Soft Body modifier (page 2–784) on top of the FFD modifier.

4. In the Properties rollout of the Soft Body modifier, choose FFD-Based.

   You can now add the body to a soft body collection (page 2–788) and simulate it as an FFD soft body.

Interface

FFD Options

- **ORIGINAL BOX**—The stable configuration for an FFD soft body is the original, non-deformed FFD box; any animation or modification of the lattice is ignored. This is the default option.

- **FRAME**—Lets you specify the state of the FFD state at a particular keyframe as the stable configuration for the object.

**Animate Transform**—When on, reactor animates both the FFD lattice and the transformation of the object. In some situations, the deformation calculated by the FFD modifier is more consistent if the object transformation follows the FFD lattice.

**Important:** Use this option only when the FFD encloses the entire mesh of the object, as the transformation applies to the whole mesh; that is, the whole object will be transformed.

Not animating the object transform can cause the FFD modifier to apply strange deformations.

Animating the object transform (turning on Animate Transform) fixes the problem.
Chapter 13: reactor

**Soft Body Collection**

Create panel > Helpers > reactor > SBCollection
Menu bar > reactor > Create Object > Soft Body Collection
reactor toolbar > create Soft Body Collection button

The Soft Body Collection is a reactor helper object that acts as a container for soft bodies. Once you have created a Soft Body Collection, you can add any soft bodies in the scene to the collection. For more information about soft bodies, see *Soft Body Modifier* (page 2–784).

When you run the simulation, the soft body collections in the scene are examined, and, provided the collections are not disabled, reactor adds the soft bodies they contain to the simulation.

**Procedures**

To create and use a Soft Body Collection:

1. Create some soft bodies by applying the reactor SoftBody modifier to standard objects.
2. Choose any of the above commands, and then click in any viewport to add the Soft Body Collection.

   **Note:** The icon’s position has no effect on the collection’s behavior.

   The collection icon is added to the scene. You can add soft bodies to the collection in two ways: by picking or by using a selection list.

3. Add objects to the collection using either (or both) of these methods:
   - On the Properties rollout, click the Pick button, and then in the viewport click an object to add.
   - On the Properties rollout, click the Add button, and then use the Select Soft Bodies dialog to specify one or more objects to add.

   **To create the collection and add objects in a single step:**
   - See the *Scripts* (page 2–817) topic.

**Interface**

**Soft Body Collection Properties rollout**

- **Highlight**—Click this button to cause the objects in the Soft Bodies list to momentarily display as if selected.
- **Soft Bodies**—Lists the names of the objects currently in the Soft Body Collection.
- **Pick**—Adds an object to the Soft Body Collection. Click this button, and then in the viewport move the cursor over the object to add to the collection. If it is a soft body, the cursor will change from an arrow to a cross and you can select the object to add it to the collection.
- **Add**—Adds one or more objects from the scene to the collection. Click the button to open the Select Soft Bodies dialog. Highlight one or more items in the list, and then click the Select button to add the objects to the collection.
- **Delete**—Removes objects from the collection. In the Soft Bodies list, highlight the bodies to remove from the collection and click this button.
Disabled—When on, the collection and in turn the bodies it contains are not added to the simulation.

Advanced rollout

<table>
<thead>
<tr>
<th>-</th>
<th>Advanced</th>
</tr>
</thead>
<tbody>
<tr>
<td>Internal Steps</td>
<td>3</td>
</tr>
</tbody>
</table>

Reset Default Values—Resets Internal Steps to its default value.

Internal Steps—Specifies how many substeps per keyframe are used to simulate the collection. Deformable bodies often require a higher level of simulation accuracy than rigid bodies, so you might need to tweak this value to get realistic results.

Procedures

To create a rope:

1. Create the spline-based shape to use to create the rope. As with all deformable bodies (page 2–777), the underlying topology of this object will influence the rope’s behavior. If the spline contains only two vertices, then the rope simulation geometry will have only a single section and will behave in a particularly un-rope-like fashion as a result. More vertices will allow the rope to bend easily and behave more realistically.

2. With the object selected, choose one of the commands listed above.

   The Rope modifier appears in the object’s modifier stack.

To edit a Rope’s physical properties:

1. Select the Rope object.

2. On the Modify panel, ensure that the reactor Rope modifier is selected in the modifier stack.
3. Use the Properties rollout to edit the properties, which are described in the Interface section, following.

**Interface**

**Modifier Stack**

</tr>
</tbody>
</table>

**Rope Type**

- **Spring**
  - Stiffness: 0.2
  - Damping: 0.2
  - Num Weaves: 1
- Keep Shape
- Constraint

**Avoid Self-Intersections**

**Start With Current State**

101 keyframes stored

**Clear Keyframes**

**Use Soft Selection**

**Reset Default Values**

**Mass**—The rope's mass in kilograms. This affects the rope behavior on collisions against other objects, its buoyancy when interacting with water, and the stretching caused by *attached rigid bodies* (page 2–798): the higher the mass of the rope, the less stretching induced by the rigid body.

**Thickness**—Lets you specify a thickness for the simulated rope, as the shape used to create the rope has no inherent thickness. A rope with a thickness of 0.0 will not be visible in the simulation.

**Friction**—The coefficient of friction for the rope's surface. As with rigid bodies, this affects how smoothly the rope will move relative to surfaces it's in contact with. The Friction values for both
objects are combined to produce a coefficient for the interaction.

**Air Resistance**—The extent to which the rope loses energy as it moves.

**Rope Type**—
- **Spring**—The default rope type.
- **Stiffness**—How much the rope can stretch.
- **Damping**—How quickly oscillations settle down when the rope is compressed or expands.
- **Num Weaves**—The extent to which the rope's inflexibility extends across vertices. For example, a value of 3 ensures that all vertices separated by three or fewer sections are subject to extra forces to stop bending. Large Num Weaves values produce an inflexible rope, whereas small values mean that only sections very close to each other will have restricted relative movement.
- **Keep Shape**—When on, the rope tries to keep its original shape, such as a spiral, rather than returning to a straight line. The effectiveness of this depends on the number of weaves (the higher of number of weaves, the stronger the shape-keeping forces).
- **Constraint**—Uses a simpler, and hence less computationally expensive, model to simulate the rope. Ropes of this type are quite stiff, and cannot be configured in the same way as ropes with a Spring type.

**Avoid Self-Intersections**—When on, the rope will not intersect with itself during the simulation. This results in a more realistic simulation, but can increase simulation time.

**Start With Current State**—The rope starts the simulation using the current state stored in the modifier. This can be useful if you have, for example, draped the rope around something in the Preview Window and then updated the viewport using Update MAX. When off, the rope starts with the state it had originally, below the modifier in the stack.

**# Stored Keyframes**—The number of keyframes, if any, stored for the rope. reactor stores keyframes for the rope if you create an animation, or if you use Update MAX in the Preview Window.

**Clear Keyframes**—Clears any stored keyframes for this rope.

**Use Soft Selection**—Allows you to use Soft Selection to smooth the transition between keyframed and simulated vertices for this deformable object. For more information, see [Soft Selection (page 2–800)](#).

**Reset Default Values**—Resets the values for this rope to their defaults.

### Constraints rollout

These options let you create a different types of deformable constraint for the body. For more
Rope Collection

The Rope Collection is a reactor helper object that serves as a container for ropes. Once you have placed a Rope Collection in your scene, you can add any ropes in the scene to the collection. You can find out more about ropes in the Rope Modifier section.

When you run the simulation, the rope collections in the scene are examined, and, provided that the collections are not disabled, the ropes they contain are added to the simulation.

Procedures

To create and use a Rope Collection:

1. Choose any of the above commands, and then click in any viewport to add the Rigid Body Collection.
   
   Note: The icon’s position has no effect on the collection’s behavior.

   The collection icon is added to the scene. You can add rigid bodies to the collection in two ways: by picking or by using a selection list.

2. Add objects to the collection using either (or both) of these methods:
   
   - On the Properties rollout, click the Pick button, and then in the viewport click an object to add.
   
   - On the Properties rollout, click the Add button, and then use the Select Rigid Bodies dialog to specify one or more objects to add.

To create the collection and add objects in a single step:

- See the Scripts (page 2–817) topic.

Interface

Rope Collection Properties rollout

Highlight—Causes the objects in the collection to flash momentarily in the viewports.

Rope Entities—Lists the names of the objects currently in the Rope Collection.

Pick—Adds an object to the Rope Collection. Click this button, and then in the viewport move the cursor over an object. If it is a Rope object, the cursor changes from an arrow to a cross and you can select the object to add it to the collection.

Add—Adds one or more objects from the scene to the collection. Click the button to open the Select Ropes dialog. Highlight one or more objects in the list, then click the Select button to add the objects to the collection.

Delete—Removes objects from the collection. In the Rope Entities list, highlight the bodies to remove from the collection and click this button.

Disabled—When on, the collection and the bodies it contains are not added to the simulation.
### Advanced rollout

<table>
<thead>
<tr>
<th>-</th>
<th>Advanced</th>
</tr>
</thead>
<tbody>
<tr>
<td>Internal Steps</td>
<td>3</td>
</tr>
</tbody>
</table>

**Internal Steps**—Because deformable objects are more complex to simulate, it is usually necessary to perform more simulation steps (page 2–709) to increase stability. This parameter specifies how many steps will be taken internally to simulate objects in this collection for each simulation substep taken globally during the simulation. For example, at 60 fps, simulating at one keyframe (step) per frame, 10 substeps, at three internal substeps for this collection, the objects in this collection will be simulated using 60x10x3=1,800 steps every second, while the simulation in general uses 60x10=600 steps per second. This allows the objects in this collection to be simulated more accurately without slowing down the rest of the simulation. In general terms, you can think of it this way:

1. Precision (stability) of overall simulation = Number of Substeps (as specified in the Preview and Animation rollout (page 2–806))
2. Precision (stability) of objects in this collection = Precision of overall simulation x (multiplied by) Internal Substeps

**Reset Default Values**—Resets Internal Steps to its default value.

---

### Deforming Meshes

A deforming mesh is a mesh whose vertices' behavior has been keyframed. The skin of a skinned character, where any deformation comes from the underlying animated character rig, could be used as a deforming mesh in reactor.

Why use deforming meshes? Firstly, rigid bodies (page 2–716) and deformable bodies (page 2–777) can collide with a deforming mesh as if it was another reactor body. The deforming mesh won't be affected by the collision, but the rigid body/deformable body will. So, for instance, you can create deformable clothes for a deforming mesh that you can drape realistically around his body, or you can cause environmental objects to react to the deforming mesh.

You can also attach deformable bodies to deforming meshes. This allows you, for example, to attach physically-simulated hair, garments, or tentacles to a keyframed character. When the character moves, its simulated elements swirl, swing, or slither (as appropriate) along with it. This is known as secondary motion, and is an easy way to add realism to your characters without having to animate the behavior by hand.

Unlike the other reactor deformable body types, you do not need to apply a special modifier to a
deforming mesh or set physical properties for it. You just have to add the shape to a Deforming Mesh Collection (page 2–794). This is because reactor itself does not deform the mesh’s vertices during the simulation: The deforming mesh is simply controlled by its current animation.

For information about how to attach objects to deforming meshes, see Constraining Deformable Bodies (page 2–795).

Deforming Mesh Collection

Create panel > Helpers > reactor > DMCollection
Menu bar > reactor > Create Object > Deforming Mesh Collection
reactor toolbar > create Deforming Mesh Collection button

The Deforming Mesh Collection is a reactor helper object that acts as a container for deforming meshes (page 2–793). Once you have placed a Deforming Mesh Collection in your scene, you can add any deforming meshes in the scene to the collection. For more information about deforming meshes, see Deforming Meshes (Skin) (page 2–793).

When you run the simulation, reactor examines the deforming mesh collections in the scene, and, provided the collections are not disabled, adds the deforming meshes they contain to the simulation.

Procedures

To create and use a Deforming Mesh Collection:

1. Create some objects to use as deforming meshes.
2. Choose any of the above commands, and then click in any viewport to add the Deforming Mesh Collection.
   
   Note: The icon’s position has no effect on the collection’s behavior.

3. Add objects to the collection using either (or both) of these methods:
   
   • On the Properties rollout, click the Pick button, and then in the viewport click an object to add.
   
   • On the Properties rollout, click the Add button, and then use the dialog to specify one or more objects to add.

To create the collection and add objects in a single step:

• See the Scripts (page 2–817) topic.

Interface

Deforming Mesh Collection Properties rollout

Highlight—Click this button to cause the objects in the collection to flash momentarily in the viewports.

Deforming Meshes—Lists the names of the objects in the deforming mesh collection.

Pick—Adds an object to the deforming mesh collection. Click this button, and then in the viewport move the cursor over an object to add...
to the collection. If it can be used as a deforming mesh, the cursor will change from an arrow to a cross and you can select the object to add it to the collection.

**Add**—Adds one or more objects from the scene to the collection. Click the button to open the Select Deforming Meshes dialog. Highlight one or more objects in the list, and then click the Select button to add the objects to the collection.

**Delete**—Removes objects from the collection. In the Deforming Meshes list, select the bodies to remove from the collection and then click this button.

**Disabled**—When on, the collection and the bodies it contains are not added to the simulation.

**Advanced rollout**

<table>
<thead>
<tr>
<th>-</th>
<th>Advanced</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Freeze</td>
</tr>
<tr>
<td></td>
<td>Reset Default Values</td>
</tr>
</tbody>
</table>

**Freeze**—When on, the deforming meshes in this collection do not follow their animation during the simulation but instead remain static. This is useful, for instance, if you want to drape clothes around a deforming-mesh-skinned character in the Preview window before using Update MAX - it’s much easier to dress a character that isn’t still walking around!

**Reset Default Values**—Resets the Freeze value to its default.

---

**Deformable-Body Constraints**

reactor modifier (Cloth/Soft Body/Rope) > Constraints rollout

As with rigid bodies, you might want to constrain the possible movement of your deformable bodies. For instance, you might want to fix cloth draperies to a position in world space, or attach deformable clothing and hair to a moveable character. However, because deformable bodies can change their shape over the course of the simulation, you can’t just specify attachment points in the object’s local space as you do with rigid bodies.

Instead, when you work with deformable bodies, you need to specify the vertices to constrain in the deformable mesh. You can then constrain the vertices using one of four deformable constraint types, which you can choose from the deformable body’s deformable Constraints rollout.

This section has separate topics for each of the following deformable constraint types:

- **Fixing Vertices in World Space** (page 2-796)
- **Keyframing Vertices** (page 2-797)
- **Attaching Vertices to a Rigid Body** (page 2-798)
- **Attaching Vertices to Deforming Meshes (Skin)** (page 2-799)

For information about using the Soft Selection option to smooth the transition between simulated and keyframed vertices for deformable bodies, see **Soft Selection** (page 2-800).

**Note:** You can constrain deformable bodies only to points in world space, rigid bodies, or deforming meshes. You can’t attach deformable bodies to “live” deformable bodies. You can, however, attach deformable bodies to other deformable bodies once they have been simulated. For example, after simulating a piece of cloth, you can remove it from...
the Cloth Collection and add it to a Deforming Mesh Collection. You can then attach any deformable body (cloth, soft or rope) to it using the Attach to Deforming Mesh constraint.

**Procedures**
The procedure for each deformable constraint type is described in its own topic.

**Interface**

Fixing Vertices in World Space

The Fix Vertices constraint lets you fix vertices in a deformable body to their current positions in world space.

**Procedures**
To fix points in a deformable body in world space:
1. On the Modify panel, click Vertex in the deformable body modifier’s sub-object list.
This lets you select individual vertices in the deformable body.

2. On the Constraints rollout, click Fix Vertices.
   A new Constrain To World constraint appears in the constraints list.
3. Ensure the constraint is highlighted in the constraints list.
4. Select the vertices to constrain.
   These vertices remain fixed in place during the simulation, while the rest of the mesh is subject to physical forces and deformation as usual.
5. When you are finished choosing vertices, it’s advisable to exit the Vertex sub-object level. This prevents you accidentally deselecting some of the constrained vertices before simulating.
6. To change the set of fixed vertices, select the object, access the modifier’s Vertex sub-object level, highlight its Constrain To World constraint in the list, and then select a different set of vertices.

**Keyframing Vertices**

This constraint allows you to make the deformable body’s chosen vertices follow their current animation.

**Procedures**

**To keyframe points for a deformable body:**

1. On the Modify panel, click Vertex in the deformable body modifier’s sub-object list. This lets you select individual vertices in the deformable body.
2. On the Constraints rollout, click Keyframe Vertices.
   A new Keyframe constraint appears in the constraints list.
3. Ensure the constraint is highlighted in the constraints list; this makes the Keyframe rollout available.
4. Select the vertices to constrain in the deformable body. During the simulation, these vertices follow the deformable body’s current animation, while the rest of the body is affected by the physical simulation as usual.
5. When finished, it’s advisable to exit the Vertex sub-object level. This prevents you accidentally deselecting some of the constrained vertices before simulating.
Interface

Keyframe rollout

[graphic]

Use Current Stored Keys—When on, the animation used for these vertices is that after the reactor modifier is applied. In other words, if the modifier contains any keyframes, reactor uses those for the animation. When off, reactor evaluates the animation before the reactor modifier is applied, thus ignoring any stored keyframes.

Attaching Vertices to a Rigid Body

The Attach To Rigid Body constraint allows you to fix vertices in a deformable body to a particular rigid body.

Procedures

To fix vertices in a deformable body to a rigid body:

1. On the Modify panel, click Vertex in the deformable body modifier’s sub-object list.

2. On the Constraints rollout, click Attach To Rigid Body.

   The new constraint appears in the Constraints list.

3. Ensure the constraint is selected in the Constraints list; this makes the Attach To RigidBody rollout available.

4. On the Attach To RigidBody rollout, click the Rigid Body pick button and then select the body to which to constrain the vertices.

5. Select the vertices to constrain in the deformable body.

   During the simulation, these vertices maintain their positions relative to the rigid body.

6. When finished, it’s advisable to exit the Vertex sub-object level, to keep from accidentally deselecting some of the constrained vertices before simulating.

Interface

Attach To Rigid Body rollout

[graphic]

Rigid Body—Displays the name of the rigid body to which the vertices are constrained. Choose a rigid body by clicking this button and then selecting a rigid body in one of the viewports.

Do not affect rigid body—When on, the attached deformable body does not affect the behavior of the rigid body in the simulation. In other words,
the points in the deformable body will follow the rigid body, but no force is applied to the rigid body from the deformable.

**Ignore Collisions**—When on, disables collision detection between the rigid body and the deformable body.

---

**Attaching Vertices to Deforming Meshes (Skin)**

attaching vertices to deforming meshes (skin)

reactor modifier (cloth/soft body/rope) > constraints rollout

The Attach To Deforming Mesh constraint allows you to fix vertices in a deformable body to a particular deforming mesh (page 2–793). This option is useful for adding physically simulated elements such as hair and clothing to an skinned character.

**Procedures**

To fix vertices in a deformable body to a deforming mesh:

1. On the Modify panel, access the Vertex sub-object level of the deformable body’s modifier.

   This lets you select individual vertices in the deformable body.

2. On the Constraints rollout, click Attach To DefMesh. The new constraint appears in the Constraints list.

3. Ensure the constraint is selected in the Constraints list; this makes the Attach To DefMesh rollout available.

4. On the Attach To DefMesh rollout, click the Deformable Mesh pick button and then select the body to which to constrain the vertices.

5. Select the vertices to constrain in the deformable body.

   During the simulation, these vertices will maintain their position relative to the deforming mesh.

6. When finished, it’s advisable to exit the Vertex sub-object level, to keep from accidentally deselecting some of the constrained vertices before simulating.

**Interface**

Attach To DefMesh rollout

- **Deformable Mesh**—Displays the name of the deforming mesh to which the vertices are constrained. Choose a deforming mesh by clicking this button and then selecting the object in one of the viewports.

- **Ignore Collisions**—When on, disables collision detection between the deforming mesh and the deformable body.
**Soft Selection**

You can use deformable constraints to specify that you want certain vertices of a deformable object to follow a user-specified animation, such as skinning, while the rest of the object is fully physically simulated. However, sometimes this can result in a visible "join" between the animated and simulated parts of a piece of cloth, soft body or rope.

To deal with this, the Cloth (page 2–778), Soft Body (page 2–784), and Rope (page 2–789) modifiers have a Use Soft Selection option. The option can help smooth transitions between the keyframed and simulated vertices.

The following illustration shows the effect of using this option. The cloth tube on the left has a keyframed top and a simulated bottom, with a visible join. The cloth on the right uses soft selection to blur the line between the two.

**Procedures**

*To use soft selection when animating a deformable body:*

1. Before you apply the reactor modifier to a deformable body, apply a modifier that has a Soft Selection option to your object, such as Edit Mesh (page 1–634) or Mesh Select (page 1–719).

You can also apply this modifier to the body later, but it's important that it be below the reactor modifier in the object's modifier stack.

2. Follow the instructions in Keyframing Vertices (page 2–797) to keyframe selected points for the deformable body, then create your reactor animation.

3. With the body selected, open the selection modifier in the modifier stack, and access the Vertex sub-object level.

4. Select the vertices that should appear fully physically simulated. For instance, for a piece of cloth where the top section is keyframed, you might want only the bottom vertices to appear to be fully affected by the physical simulation.

5. On the Soft Selection rollout, turn on Use Soft Selection.

6. Set the Falloff value to specify a smooth falloff from the selected vertices to the unselected ones.

   This is represented visually in the viewport.

7. Now open the reactor modifier and turn on Use Soft Selection.
When you run the animation, your specified falloff will be used to blend smoothly between the keyframed and simulated vertices.

This section covers the following topics:

- The Water Space Warp (page 2–801)
- Rendering Water (page 2–803)

Water

The reactor Water object allows you to simulate the behavior of a water surface. Objects can interact with the water in physically realistic ways, creating waves and ripples. reactor calculates a buoyancy value for any objects that fall into the water using their mass and size, so that some objects sink and others float. You can even change the density of a water object, which affects how objects float in it.

Water in reactor is a space warp (page 3–1014) that is simulated as water. Space warps don’t render, so you need to provide reactor with a geometrical representation of the water if you want it to appear in your final animation. You do this by binding a plane or other geometry to the space warp. Note that a representation of the water still appears in the Preview Window even if you haven’t done this.

Procedures

To create a Water space warp:

1. Choose one of the above commands, and then in any viewport drag out a Water object.

   Tip: For horizontal water, create the space warp in a Perspective or Top viewport.

2. Move and rotate the object as necessary using standard commands. For changing other properties, see the next procedure.

To edit the properties of a Water object:

1. Select the object in the scene.

2. On the Modify panel, open the Properties rollout.
3. Use the rollout to specify properties, as described in the Interface section.

**Interface**

**Size X/Y**—The dimensions for the water object.

**Subdivisions X/Y**—The tessellation for the water’s mesh.

**Landscape button**—Although water is defined using a rectangular area, you can simulate non-rectangular surfaces and obstacles inside the water by defining a landscape geometry. Once you designate landscape geometry, any vertex in the Water space warp that are contained in the landscape are fixed during the simulation and waves and ripples will be reflected at those points.

**Wave Speed**—The speed at which wave crests propagate across the surface of the water.

**Min/Max Ripple**—Limits on the size of the waves generated in the water.

**Density**—The relative density of the liquid. This determines which objects will sink into the water, and at what height objects of a lesser density will float. The density is specified relative to the density of water (1.0=1,000 kg/m³).

**Viscosity**—Resistance to flow; how difficult it is for objects to move through the liquid. A high value means that the motion of objects through the water is highly damped.

**Depth**—The depth of the water. Buoyancy is applied only to objects inside the water.

**Use Current State**—When on, the simulation uses the current animation to calculate the starting state. So if you have, for example, updated the water during the preview (page 2–815) using the Update MAX command, the stored state is used as the initial state.

**Disabled**—Removes the water from the simulation.

**# Stored Keyframes**—This indicates if there are any keyframes stored for the water. Keyframes are stored for the water if you create a reactor animation in 3ds Max, or if you use Update MAX in the Preview Window.

**Clear Keyframes**—Clears any stored keyframes for this water.

**Show Text**—When off, the label "Water" doesn’t appear next to the space warp in the viewports.

**Reset Default Values**—Restores the default values for the object.
Rendering Water

Water in reactor is defined using a space warp. Space warps don’t render, so if you want the water to appear in your final animation, you need to provide reactor with a geometrical representation of the water. To do this, you need to bind a plane or any other planar geometry to the water. The plane will deform according to the Water space warp (page 2–801), and you can then render it as part of your scene.

Binding an object to the water applies a modifier to that object, which lets you set a scale strength for the deformation. For example, if you set this scale value to 2.0, any water deformation is doubled for the vertices in the object.

Procedures

To bind a plane to reactor Water:

1. Draw a plane the same size as your water in the viewport. Put it in a different place so you can easily link the two.

2. Click the Bind To Space Warp button on the main toolbar.

3. In the viewport, drag from the plane to the water space warp, or vice-versa.
   The reactor Water (WSM) modifier appears in the plane’s modifier stack.

4. Move the plane to the same position and orientation as the space warp (or vice-versa).

Interface

Water WS Modifier Properties rollout

- Scale Strength—Acts as a multiplier for the geometry’s deformation by the water. Increases or decreases the deformation applied by the Water space warp (page 2–801).
- Reset Default Values—Returns Scale Strength to its default value: 1.0.

Wind

The Wind helper object lets you add wind effects to reactor scenes, allowing you, for instance, to make curtains flap in the breeze. After adding the helper to your scene, you can configure various properties for the effect such as its speed, gusts,
and whether objects in your scene can be sheltered from the wind. You can animate most of these parameters. The orientation of the helper icon indicates the direction of the wind: It blows in the direction of the weathervane arrow. You can also animate this direction by animating the icon’s orientation.

Procedures
To add wind to a scene:
1. Choose one of the above commands, and then click in any viewport to add the Wind helper.
   Note: The icon’s position has no effect on the wind’s behavior unless you activate the Use Range option.
2. Use the Rotate tool to rotate the icon and set the wind direction.
   The wind blows in the direction indicated by the weathervane arrow.

Interface
Wind Properties rollout

- Properties

- Use Range

- Enabled Sheltering

- Applies to

- Disabled

- Display

- Size

- Reset Default Values
Wind On—[Animatable] Defines whether the wind forces are applied or not.

Wind Speed—[Animatable] The strength of the wind force. The direction is specified by the icon’s orientation, which is also animatable.

Perturb Speed—When on, the strength of the wind varies over time, using the following parameters.

- Variance—The maximum amount of change in the speed.
- Time Scale—How quickly speed change occurs, with small values producing slow changes, and large values producing rapid changes.

Ripple—[Animatable] When on, the wind direction becomes a function of space and time, allowing you to add rippling effects to cloth objects affected by the wind. This effect can occur in the Left/Right, Up/Down, or Back/Forward directions, where Forward is the wind direction and Up is the up-axis of the wind icon.

- Magnitude—The directional variance for the ripples.
- Frequency—The regularity of ripple formation.
- Perturb Time—When on, the spatial perturbation is itself perturbed over time, meaning that the ripples move back and forth. The Perturb Time feature has its own Magnitude and Frequency parameters. When off, the rippling cloth should eventually come to rest, unless Perturb Speed is on.

Use Range—[Animatable] When on, the wind effect has the specified range of action, starting from the icon. The range limit is displayed in the viewport, as depicted in the following illustration.

- Fall Off—The extent to which the wind effect falls off towards its range limit. You can choose from None, Inv (strength decreases proportionally to distance), and Inv Sq (strength decreases proportionally to the square of the distance).

Enable Sheltering—[Animatable] When on, objects can be sheltered from the wind by other objects.

Applies To—These check boxes allow you to specify the types of objects that are affected by the wind. You can choose from Rigid Bodies, Cloth, Soft Bodies, and Ropes.

Disabled—Removes the wind from the simulation.

Display—The size of the wind icon in the viewports.

Reset Default Values—Resets the default property values for this Wind helper.

The reactor Utility

You can access much of reactor’s functionality through the reactor utility. It lets you preview the simulation, change world and display parameters, and analyze the convexity of objects. It also lets you see and edit the rigid body properties associated with objects in the scene. Perhaps most
important, it lets you switch between the Havok 1 and Havok 3 engines.

The utility is divided into a number of rollouts. For more information, follow the links. More information about the two different Havok versions is available later in this topic, in Differences between Havok 1 and Havok 3 (page 2–806).

- About: Choose Havok 1 or Havok 3 solver
- Preview and Animation (page 2–806)
- Havok 1 World/Havok 3 World (page 2–808)
- Collisions (page 2–810)
- Display (page 2–812)
- Utils (page 2–813)
- Properties (page 2–815)

Differences between Havok 1 and Havok 3

You can use either of two different dynamics solvers in reactor: Havok 1 or Havok 3. To switch between them, choose the desired solver from the drop-down list on the About rollout. The active solver is saved with the scene file.

Note: If you preview a simulation or create an animation using Havok 3 and the scene contains non-supported entities such as soft bodies, reactor simply ignores these entities and excludes them from the simulation.

Preview & Animation Rollout

Utility panel > reactor > Preview & Animation rollout

This rollout lets you run and preview your reactor simulation, as well as specifying timing parameters for the simulation.
Start Frame—When creating a world to be simulated or previewed, reactor needs to access the objects in 3ds Max at a fixed point in time. This parameter defines this point in time (in 3ds Max frames). Initial shapes, positions and velocities are taken from the actual shapes, positions and velocities of the objects in the scene at this particular frame. When creating an animation, keyframes are created starting from this frame to the End Frame time.

End Frame—The last frame to simulate. When reactor creates an animation, it generates keyframes from the Start Frame time to this frame.

Frames/Key—The number of frames for every keyframe that reactor creates (time step). For example, a value of 2 will create a keyframe every other frame. Increasing this value forces reactor to take bigger time steps, potentially reducing the accuracy of the simulation; you might need to then update the Substeps/Key setting accordingly (see following).

Substeps/Key—The number of reactor simulation substeps per keyframe (that is, per time step). The higher this value, the more accurate the simulation will be, although it will also require more computation to simulate. For information about time steps and substeps, see Time Steps (page 2–709).

Time Scale—This parameter maps between time in the simulation and time in 3ds Max. Changing the value lets you slow down or speed up the animation. Values less than 1.0 produce slow-motion animations, while values greater than 1.0 produce sped-up animations.

Create Animation—Runs the simulation and creates keyframes, starting from Start Frame and ending at End Frame.

Update Viewports—When on, updates the scene in the viewports as the animation is created.

Create List/Layer—When on, creates a List controller (page 2–342) (unless one is already present) for the position and rotation tracks of those rigid bodies using Position/Rotation/Scale transform controllers. A new subcontroller is added to the List controller to hold the keys created by reactor. This new controller is weighted to 100, while the previous controllers are weighted to 0. In the special case of rigid bodies belonging to a character studio Biped (page 2–843), a new biped layer is created every time a reactor animation is generated.

Preview Animation—Previews the simulated scene in the Preview Window (page 2–815).
Havok 1 World/Havok 3 World Rollout

Utility panel > reactor > Havok 1 World/Havok 3 World rollout

This rollout lets you set some general parameters for your simulated world, such as the strength and direction of gravity, the scale of the world, and how easily objects can collide with each other. When Choose Solver is set to Havok 1, the rollout name is Havok 1 World, and when Choose Solver is set to Havok 3, the name is Havok 3 World.

Interface

The only difference between the two different versions of the Havok World rollout is that the Havok World 3 rollout contains an extra group of parameters at the end, named Simulation. The following illustration shows the Havok 3 version of the rollout.

Gravity—The acceleration, in world units, the objects in a scene have due to gravity. It is an important value because it affects the overall feeling of scale in a dynamics simulation. reactor will generate a warning if you specify a non-standard Gravity value compared to World Scale (see following); that is, if you set the value much higher or lower than –9.8 m/s², where m is World Scale’s representation of one meter. The
warnings are provided for guidance and can be safely ignored if you are happy with the behavior of your animation. The default Gravity value reflects "real-world" gravity: –9.8 m/s² (–386.22 inches/s²) on the Z axis. For more information, see Scale (page 2–711).

**World Scale**—The distance in 3ds Max world units, that represents one meter in the reactor world, and hence determines the size of every object in your simulation.

*Note:* Changing the World Scale value can drastically alter simulated objects' behavior. For more information, see Scale (page 2–711).

**Col. Tolerance**—(Collision Tolerance) One of the tasks that reactor performs at each simulation step is detection of whether any objects in the scene are colliding, and then updating the scene accordingly. If objects are closer together than the Collision Tolerance value, reactor considers them to be colliding. A high Collision Tolerance value results in a stable simulation, but it can also cause gaps between "colliding" objects.

The default value is 1/10th of World Scale (10 cm if you are modeling using real-world sizes), and it is a good rule of thumb to always keep it above 1/40th (4 mm), due to floating point precision limits in the processor. For standard scenes and object sizes, the default parameters for world scale and tolerance should be adequate. If you are simulating very small objects where the tolerance is still too visible, try reducing the World Scale value and the Collision Tolerance and Gravity accordingly. For more information, see Scale (page 2–711).

**Add Deactivator**—When on, reactor adds a deactivator to the simulation. The deactivator keeps track of the objects in the simulation and deactivates (stops simulating) objects that it determines are at rest. This keeps reactor from wasting system resources simulating objects that aren't doing anything. When Add Deactivator is on, you have access to two distance parameters for determining whether an object is moving or not. The reason that there are two properties rather than just one is for bodies that vibrate. It's possible that a body can end up vibrating after a collision or some other occurrence. A vibrating body might vibrate a few millimeters in distance, which would keep it active for a typical Short Frequency test. However, the object is not really moving anywhere, so keeping it active wastes CPU time. However, if it vibrates in place, it fails the Long Frequency test and is deactivated.

- **Short Frequency**—The minimum distance, usually in millimeters, that an object must move during each step of a simulation. If an object in a simulation does not move the specified distance in each step, reactor deactivates it.
- **Long Frequency**—Also sets a distance, usually larger than the Short Frequency value. Long Frequency checks every few steps simulation rather than at every step. Any object that does not move the required Long Frequency distance is deactivated.

**Add Drag Action**—When on, ensures that rigid bodies are subject to constant drag. This damps their linear and angular velocities, so they come to rest sooner. This is useful, for example, where rigid bodies are joined with constraints (page 2–724), as it helps the constrained bodies to come to rest despite the forces applied by the constraints.

- **Lin**—The linear damping applied by Add Drag Action.
- **Ang**—The angular damping applied by Add Drag Action.

**Do Not Simulate Friction**—When on, reactor ignores all Friction values during the simulation, and objects slide easily across each other.

**Fracture Penetrations**—These parameters let you adjust how reactor simulates Fracture objects. For
Simulation group

These controls are available only with the Havok 3 engine.

The first lets you choose how reactor computes the simulation:

- **Discrete**—reactor checks for collisions only at the beginning and end of each simulation step. This is faster but less accurate.
- **Continuous**—reactor checks for collisions constantly, throughout each step. This is the default choice, and results in slower but highly accurate simulations. This option significantly reduces the chances of missed collisions.

Max Linear Vel.—The assumed maximum linear velocity for all bodies.

This does not set objects’ linear velocity. If, later on, a rigid body’s velocity significantly exceeds this value, it might tunnel through other objects even if its Quality property is set to Critical.

The default value is 200 meters/second. This value is used during continuous simulations by the collision solver to optimize the simulation, so if it can assume a maximum linear velocity it can discard several cases and get a solution faster.

Stiffness—The hardness of the constraints in the scene.

Use this parameter to configure the dynamics solver. When constraints used in the scene are very hard or stiff, set this to Hard; the Soft or Medium setting works most other cases. Setting Stiffness to Soft can lead to unstable solutions if the constraints are too stiff.

Tip: Another way to reduce the stiffness of the simulation is by lowering the Strength value of constraints, thus relaxing the constraints.

Collisions Rollout

Utility panel > reactor > Collisions rollout

These settings let you store collision details from your scene, and enable and disable collision detection for specific pairs of objects. Pairs of objects with collisions disabled pass through each other during the simulation. Disabling collisions can be useful when you have objects that are attached together, such as the wheels of a car and its chassis. This means reactor doesn’t check for every small collision between the objects, which can slow down the simulation.

Interface

Collisions rollout

<table>
<thead>
<tr>
<th>Store Collisions:</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image" alt="Store Collisions" /></td>
</tr>
</tbody>
</table>

Filter before storing

- Objects...
- Velocity > 0.0

Global Collisions

- Define Collision Pairs
- Selected Pair
  - Enable
  - Disable

Store Collisions—See Storing and Accessing Collisions (page 2–774).
Filter Before Storing—See Storing and Accessing Collisions (page 2–774).

Define Collision Pairs—Opens the Define Collisions dialog (page 2–811). This allows you to toggle collision detection between specified pairs of objects. Pairs of objects with disabled collisions pass through each other during the simulation.

Selected Pair: Enable—Lets you quickly enable collisions between the selected pair of objects. This button is available only when both objects are part of a collection (not necessarily the same collection) and their collisions are currently disabled.

Selected Pair: Disable—Click this button to quickly disable collisions between the selected pair of objects. This button is available only when both objects are part of a collection (not necessarily the same collection) and their collisions are currently enabled (the default condition).

Define Collisions Dialog

Entities—Lists the names of the reactor bodies in the scene (any object added to a collection). Highlighting one object populates the Enabled Collisions and Disabled Collisions lists for that object with respect to the other bodies in the scene. If you select more than one object in this list, how the Enabled/Disabled lists are populated depends on the value of Common Collisions.

Common Collisions—When on, if more than one object is highlighted in the Entities list, the Enabled and Disabled lists are populated from the list of possible pairs that can be made using only the highlighted objects. When off, the lists contain all possible pairs from the scene that contain at least one of your selected objects.

For example, take a scene containing four bodies: Box01, Box02, Box03, and Box04. If Common Collisions is on, and you then highlight Box01 and Box02 in the Entities list, then the only possible pair that just includes your selected objects is Box01<->Box02.

If you highlight Box01, Box02, and Box03, the possible pairs using these objects are Box01<->Box02, Box02<->Box03 and Box01<->Box03. If you highlight the same objects with Common Collisions off, then the lists also include the highlighted objects paired with the remaining objects in the collection. This means that the available pairs would now include Box01<->Box04, Box02<->Box04 and Box03<->Box04.

This option is on by default.

Enabled Collisions—Lists pairs with collisions enabled.

Disabled Collisions—Lists pairs with collisions disabled.

Disable Selection (Right Arrow)—Moves pairs highlighted in the Enabled list to the Disabled list.

Disable All (Double Right Arrow)—Moves all pairs in the Enabled list to the Disabled list.

Enable Selection (Left Arrow)—Moves the pairs highlighted in the Disabled list to the Enabled list.

Enable All (Double Left Arrow)—Moves all pairs in the Disabled list to the Enabled list.

OK—Closes the dialog, saving any changes carried out while the dialog was open.

Cancel—Closes the dialog without saving changes.
Display Rollout

Utility panel > reactor > Display rollout

This rollout lets you specify display options for previewing (page 2–815) your simulation, including cameras and lighting. These options have no effect on the actual behavior of the final animation; they affect only the appearance of the preview window (page 2–815).

Interface

Camera—Click this button and then pick a camera from the viewports to use as the initial view for the display. Your chosen camera’s name appears on the button. If you don’t assign a camera, the settings on the current Perspective viewport (if any) are used initially in the Preview Window.

Camera Clipping Planes—If a camera is assigned, the display tries to use the camera to generate clipping planes. If no camera is assigned, reactor uses default values for the clipping planes in the display.

Use Defaults—It is possible that the clipping planes for your specified camera are not sufficient to display everything in the scene. Rather than having to change these values in the window every time the simulation is run, you can turn off Use Defaults and then specify your own clipping planes using the Near Plane and Far Plane values.

- Near Plane—The near plane to be used when Use Defaults is off.
- Far Plane—The far plane to be used when Use Defaults is off.

Lights—Lists the scene lights reactor uses for the preview. When the list is empty, reactor creates and uses a flashlight at the camera position; you can toggle this light from the Preview Window > Display menu. You can combine up to six omni lights or spotlights to create the preview lighting. Choose lights from the scene one at a time with the Pick button, or add from a list of the available lights in the scene using the Add button. To remove a light from this list, highlight it in the list and then click Delete.

Texture Quality—The size (NxN pixels) of the textures generated for use in the display. A smaller value uses less memory.

Mouse Spring—These options allow you to configure the spring used when you select objects with the right mouse button (Havok 1) or Spacebar (Havok 3) in the preview window (page 2–815).

- Stiffness—The stiffness of the mouse spring. If the mouse spring is too strong you might be able to pull objects through each other;
this won’t cause errors, but it can create an undesirable state. Default=30.0.

- **Rest Length**—The rest length of the mouse spring. Default=0.0.
- **Damping**—The damping value for the mouse spring. Default=1.0.

**Use DirectX**—When on, the 3D rendering in the preview window uses the DirectX system. When off, the window uses OpenGL.

### reactor Utilities

Utility panel > reactor > Utils rollout

menu bar > reactor > Utilities

reactor provides a number of helpful utilities that you can use to analyze and optimize your simulation. For instance, you can check your reactor world for the presence of any unusual physical states that might cause problems with the simulation, such as excessive gravity, and you can remove redundant keyframes from a generated animation.

You can also access these utilities from the reactor menu.

### Interface

**Analyze World**—This utility begins by creating a simulation. If it finds any errors while constructing the simulation, such as invalid numbers of objects in systems or invalid meshes that would stop the simulation from running, it reports these in a dialog. These error checks are always carried out when creating a simulation, and if any of the tests fail the simulation cannot continue.
If your simulation passes the initial error checks, the world analysis begins. This checks for unusual physical states that could cause issues in simulation, such as interpenetrating objects or extreme values for gravity or object density. If any such states are found, the utility reports them in a window and gives you the option to continue or cancel. If you are trying to simulate, choosing Continue runs the simulation; otherwise it closes the window.

**Analyze Before Simulation**—When on, reactor always calls Analyze World before previewing or running the simulation. Default=on.

**Stop Simulation on Warnings**—When on, prevents reactor from creating an animation if any warnings occur during analysis. For example, if the analysis finds that a body’s property such as Friction exceeds the bounds of real-world values, it halts generation of the animation. Has no effect on the Preview process. Default=off.

**Report Problems After Simulation**—When on, reactor reports problems detected during the simulation after it’s finished. Default=on.

**Analyze on Solver Switch**—When on, reactor automatically calls Analyze World when you change the solver from the About rollout. Default=on.

**Save Before Simulation**—When on, reactor saves your scene before simulating.

**Suppress Animation Warning**—When off, and you click Create Animation, reactor opens an alert warning you that animation creation cannot be undone, and asking you to confirm. When off, reactor simply creates the animation without warning you. Default=off.

**Key Management group**
After generating an animation with reactor, you often end up with a number of redundant keyframes. For instance, in a scene with a rolling rigid body, creating the initial animation might result in a keyframe for every frame. However, you can actually specify the body’s animation with keys at just a few frames (perhaps frames 0, 25, and 90), allowing 3ds Max to interpolate frames between them. This utility allows you to remove any redundant keyframes for specified objects, thus saving memory. This functionality applies only to rigid bodies.

**Reduction Threshold**—Specifies how aggressive the key reduction is. Increasing this value causes more keys to be deleted, but the animation might lose fidelity. Lowering it retains more keys with greater accuracy, at the cost of memory. Default=0.5.

**Reduce After Simulation**—When on, reactor automatically applies keyframe reduction each time you simulate.

**Reduce Now**—Reduces keyframes for all the rigid bodies in the simulation.

**Delete All Keys**—Deletes all keyframes for all the rigid bodies in the simulation.

**Selection group**

**Test Convexity**—Performs a convexity test on the object currently selected in the viewport, allowing you to check whether the object is convex or concave (page 2–719) before choosing a simulation geometry (page 2–719).

**Delete Keys**—Deletes all keyframes for the objects currently selected in the viewport.

**Reduce Keys**—Reduces keyframes for the objects currently selected in the viewport.
Properties Rollout

Utility panel > reactor > Properties rollout
reactor toolbar > Open Property Editor

For details of this rollout, see Rigid Body Properties (page 2–717).

The Real-Time Preview

Utility panel > reactor > Preview and Animation rollout > Preview Animation button
Menu bar > reactor > Preview Animation
reactor toolbar > Preview Animation button

It’s useful to be able to preview reactor simulations from within 3ds Max. The Preview Window lets you view and interact with a simulation in real time. You can run the simulation, interact with the objects in the scene using the mouse, and even update your objects in 3ds Max with their current state in the preview.

Procedures
To preview a simulation in the Preview Window:
1. Choose one of the above commands.
2. If no errors are found in your current scene setup, the Preview Window opens with your scene.
3. Press P to start the simulation.

At any time during the simulation, you can orbit around the scene by left-button dragging the mouse within the Preview Window. With Havok 1 and Havok 3, you can pan the window by middle-button dragging; with Havok 3, you can also pan the window by right-button dragging.

To interact with objects in the Preview Window:
1. Position the mouse cursor over the object you want to interact with, and then press and hold the right mouse button (Havok 1) or the Spacebar (Havok 3).

This creates a reactor spring between the mouse cursor and your chosen object.
2. While holding the right mouse button (Havok 1) or the Spacebar (Havok 3), move the mouse.

This drags the object, letting you pull it around, unless it’s a fixed object, or attached to one, and interact with other objects in the scene.
3. To release the object, release the right mouse button (Havok 1) or the Spacebar (Havok 3).

To update 3ds Max from the Preview Window:
1. Preview the simulation as described above.
2. When the scene is in your chosen state (for instance, you might want to drape some clothing over a figure, or let some objects fall and roll on the ground), open the MAX menu and choose Update MAX.

Note: The scene in 3ds Max will not be refreshed until you close the Preview Window.

Interface
Preview Window Menus
Timing

At the bottom of the window, profiling and timing information is shown:

The information presented is:

- The current *time step (simulation step)* (page 2–709) used for the simulation. This value is initially taken from the *Preview & Animation rollout* (page 2–806) but can also be changed by using the *Performance menu* (page 2–817).

- The number of *substeps* (page 2–709) used for the simulation. Again, this value is initially taken from the *Preview & Animation rollout* (page 2–806) but can also be changed by using the *Performance menu* (page 2–817).

- The current simulation time; that is, the time that the current image in the preview represents in the final animation.

During the preview, reactor tries to run the simulation in real time. In other words, if a simulation step of one second takes only 0.7 second of CPU to simulate, reactor "waits" 0.3 second before simulating the next step. That way, the animation is presented in the window at the same speed as the final animation in 3ds Max.

However, for complex scenes or slow CPUs, simulating a particular period of time can take actually more CPU time than the specified period. For example, a simulation step of one second might actually take two seconds to calculate. In that case, it is not possible to present the animation in real time, and the animation is therefore presented during the preview at a slower speed that the final animation will have once it has been created. When this happens, the preview reports it by appending an asterisk (*) to the current time:

Simulation menu

- **Play/Pause** (P)—Starts and pauses the simulation. If the simulation is paused, the display remains active and you can still pan, rotate, and zoom the camera, but the physics world remains still.

- **Reset** (R)—Resets the simulation, returning objects to their initial positions.

Display menu

*Important:* When About rollout > Choose Solver is set to Havok 3, only Camera Settings is available from this menu.

- **Camera Settings**—Opens a dialog that allows you to specify the near and far clipping planes for the camera, and to change the camera’s field of view (F.O.V.). The clipping planes can also be set externally from the reactor utility Display rollout.

- **Faces**—When on, the faces (and not the edges) of the display bodies are rendered.

- **Wireframe**—When on, the edges (and not the faces) of the display bodies are rendered.

- **Sim Edges**—When on, the edges of the physically simulated geometry (the simulation geometry for each body) are rendered in the preview window. This is useful for seeing what’s physically happening in a simulation.

- **Grid**—When on, three 2D grids are displayed in the XY, YZ and ZX planes.

- **Origin**—When on, the X (in red), Y (in green) and Z (in blue) axis are displayed at the origin (0,0,0).

- **Flashlight On/Off**—When on, a flashlight located behind the camera lights the scene. When off, lights defined on the Display rollout of the utility are used. If no lights are defined, the preview uses a single fixed light.
Performance menu

**Fixed Step (60,50,40,30 fps)**—Choosing one of these options changes the frequency of the simulation to the given value; a frequency of 30 fps yields a time step of 1/30 (0.0666) second, 50 fps means a time step of 1/50 (0.02) second, etc.

**Substeps (1-100 substeps)**—Choosing of these options sets the number of substeps taken in every simulation step.

Mouse menu

This menu is available only when using the Havok 1 engine.

**Pick at C.O.M.**—During the preview, you can pick and drag objects (see To interact with objects in the Preview Window: (page 2–815). A spring is the attached between the mouse cursor in the screen and the object. When this option is on, the spring is attached to the center of mass of the object. Otherwise the spring is attached to the point on the object where you first right-clicked.

**Mouse Help**—This option shows some help regarding the use of the mouse to control the camera and mouse picking.

**MAX**

**Update MAX**—Takes the position and rotation of the objects in the simulation and uses them to update the objects in 3ds Max.

**Use MAX parameters**—Resets the substeps and time step (FPS) values to the values set in the reactor utility’s Preview and Animation (page 2–806) rollout.

Display rollout

The Display rollout of the reactor utility lets you configure various display options for the Preview Window, including cameras and lighting. For more information, see Display Rollout (page 2–812).

---

**Scripts**

This section deals with some useful scripts that you can use to speed up your creation of reactor scenes.

If you are interested in creating your own scripts, see the MAXScript Reference, available from the 3ds Max Help menu.

**Setup Scripts**

These scripts allow you to quickly set up constraints and collections. They are run automatically when you follow the specified procedures.

**Constraint Creation**

This applies to all the reactor constraint (page 2–724) types, except the Point-to-path constraint (page 2–762).

**To create a constraint and attach objects in a single step:**

This method works with two or more objects only; it doesn’t work with a single-body constraint setup such as Spring with a child only.

1. Create the object(s) to constrain, and then ensure they are both selected.

   If you select more than two objects, reactor will create constraints between them. If you link the objects together hierarchically in 3ds Max before creating the constraints, reactor will create constraints between link parents and children. Otherwise, reactor will examine the scene and try to choose appropriate pairs of objects.

2. Create the constraint(s) by using the reactor toolbar, menu or quad menu. The constraint automatically appears in the viewport, and as you will see in the constraint’s Properties rollout, your objects are now attached to the constraint.
If the objects are linked in 3ds Max, reactor will automatically make the link’s child object the constraint child and the link parent the constraint parent. Otherwise, reactor will examine the scene and try to choose an appropriate parent and child.

In addition, if the constrained objects are already added to a collection, reactor will disable collisions between them (except in the case of springs (page 2–727)).

**Collection Creation**

This applies to all the reactor collection types: rigid body collections (page 2–723), soft body collections (page 2–788), cloth collections (page 2–781), and rope collections (page 2–792). It also applies to the Fracture (page 2–770) and Constraint Solver (page 2–736) helpers.

**To create a collection and add bodies in a single step:**

1. Create the object(s) to add to the collection, then ensure that they are all selected.
2. Create the collection by using the reactor toolbar, menu or quad menu. The collection automatically appears in the viewport, and as you will see in the collection’s Properties rollout, your objects are now added to the collection.

**The Rag Doll Script**

This example script lets you quickly set up a simple humanoid character, using a mixture of Rag Doll (page 2–737) and Hinge (page 2–747) constraints to limit the movement of the character’s limbs. You can use the sample humanoid, or create your own character using the provided naming conventions and the script will set up its constraints. Alternatively you can use the script as a basis for creating your own custom rag doll script.

**Procedures**

**To create the sample rag doll:**

1. Run this script:
   - menu bar > MAXScript > Run Script > rctRagDollScript.ms
   - Utilities panel > MAXScript > Run Script > rctRagDollScript.ms

   The Ragdoll dialog opens, with two rollouts: Create Humanoid and Constrain Humanoid.

2. On the Create Humanoid rollout, ensure that your chosen creation options are on, and then click Create Humanoid. A humanoid figure appears in the viewport.

3. To set up the humanoid’s constraints, ensure that your new humanoid is highlighted in the Humanoids list on the Constrain Humanoid rollout (by default, it’s called Ragdoll) and that your chosen options are active on the rollout.

4. Click Constrain Humanoid.

   The script creates Rag Doll constraints and Hinge joints with appropriate limits for the humanoid. In addition, if Create RBCollection and Create CSolver are on, the script creates these helpers and adds the bodies and constraints to them.
To turn your own humanoid figure into a constrained rag doll:

1. Create your figure using the naming conventions described in How It Works (page 2–820).
2. Run the script as described above.
   The script searches the scene for geometry that follows the naming conventions and adds your figure to the Humanoids list.
3. Ensure your figure is highlighted in the list and then click Constrain Humanoid.

Interface

Create Humanoid rollout

Name Root—This text box stores the root name for the objects to be created. For example, the Name Root "RagDoll" generates objects with names such as RagDoll Pelvis and RagDoll R UpperArm.

Height—The height of humanoid to be created.

Vertebra—The number of vertebra to be created in the character’s spine.

Add Hands—When on, reactor creates boxes for the character’s hands.

Add Feet—When on, reactor creates boxes for the character’s feet.

Link Parts—When on, reactor links the created parts as a 3ds Max hierarchy.

Create Humanoid—Click to create the humanoid objects and add them to the scene.

Constrain Humanoid rollout

Humanoids—Displays a list of potential humanoids found in the current scene that could be used for creating rag dolls. In generating this list only the root node is examined so it is, in effect, a list of valid root nodes in the scene. If the rest of the hierarchy does not exist for a given root, when you use the root to create a rag doll the software outputs errors to the MAXScript listener.

Vertebra—The maximum number of Rag Doll constraints that the script creates for the character’s spine. If this value exceeds the number of valid vertebrae in the selected humanoid, the script won’t create the excess constraints.
Create RBCollection—When on, the tool creates a Rigid Body Collection (page 2–723) and places all the parts of the newly created rag doll character into it.

Create CSolver—When on, the script adds a Constraint Solver (page 2–736) to the scene, which is then associated with the freshly created Rigid Body Collection. All the hinges and rag doll constraints that are created for the selected humanoid are added to this. This option is available only if you have chosen to create a Rigid Body Collection.

Add Hands—When on, if the selected humanoid has hands, the script creates constraints to connect the humanoid’s hands to the rest of the body.

Add Feet—When on, if the selected humanoid has feet, the script creates constraints to connect the humanoid’s feet to the rest of the body.

Snapshot Parts—When on, the script creates a separate geometry object for each object to be attached to a constraint. It is the newly created snapshot that is then used in the constraint and added to the collection (if a collection is being created).

Link To Original—When on, the newly created snapshot geometries are linked to the original geometries. Available only when Snapshot Parts is on.

Change Name—When on, each geometric component of the new rag doll is prefixed with the text in the New Name field. Available only when Snapshot Parts is on.

New Name—When on, each geometric component of the new rag doll is prefixed with the text in the New Name field.

Constrain Humanoid—Click to create the Rag Doll constraints and, depending on the active options, also create a copy of the source objects, a Rigid Body Collection, and a Constraint Solver.

How It Works

The script works by assuming that you’ve used the following naming conventions for the rag doll parts. This naming convention follows that used by the character studio Biped object to name the limbs. However, as long as they are named as following, you can use any geometry created in 3ds Max. The script scans the selection for geometry with names that include one of the following:

- _R_UpperArm
- _R_ForeArm
- _L_UpperArm
- _L_ForeArm
- _R_Thigh
- _R_Calf
- _L_Thigh
- _L_Calf
- _Pelvis
- _Spine
- _Head

The script assumes that there is only one of each type of part, except in the case of the spine, which can have up to five parts.

At this point the adjoining parts are connected, using mostly Rag Doll constraints (page 2–737). However, the script also uses Hinges (page 2–747) for the elbow and knee joints, as using Rag Doll constraints would be overkill to achieve the simple constrained motion found in an elbow joint. The script also sets suitable limits for each constraint.

In addition, the script sets the mass of each rigid body in the character to 10.0 kilograms, and the simulation geometry to be a bounding box. It also disables collisions between constrained pairs of bodies.
Can I assign initial velocities to objects? How?

Yes. At the start of the simulation, reactor assigns to each object the velocity it currently has in 3ds Max. In other words, if an object is moving during the frame range A to B, and you start the reactor animation setting Start Frame (page 2–806) in between A and B, the object will start with the velocity it had in your animation.

**Warning:** Make sure the object has the desired velocity at the exact frame where reactor starts the simulation (Start Frame). Since 3ds Max usually decelerates an object when animating its movement using keys at time A and B, starting the reactor animation at time B won’t add any velocity to the reactor simulation. In order to have initial velocity in the reactor animation, start at a frame between A and B.

Is it possible to modify the animation in Cloth/Soft/Rope/Water?

The animation for Cloth, Soft (mesh), and Rope is internally stored in the respective modifier using a memory-optimized format. Unfortunately, there is no direct access to those keyframes. However, you can use the Point Cache modifier (page 1–758) to do some manipulations.

There is some MAXScript access to Water keyframes. For details on MAXScript, choose Help > MAXScript Reference.

What happened to Point-Nail constraint?

The Point-Nail constraint from reactor 1 has been superseded by generalizing the Point-Point constraint (page 2–750). The old Point-Nail constraint is equivalent to a single bodied Point-Point constraint.

Can I apply the Cloth/Soft/Rope modifier to part of a mesh?

While the Soft, Cloth, and Rope (page 2–777) modifiers apply to all the vertices, you can fix or keyframe vertices of the mesh or spline by using deformable constraints (page 2–795). Fixed or keyframed vertices will not be simulated physically.

Can I apply the Cloth/Soft/Rope modifier to more than one object?

In general, no, because the animation is stored explicitly in a single modifier. The only exception is the FFD soft body (page 2–786): If you have an FFD modifier applied to more than one object, you can apply a reactor Soft Body modifier (page 2–784) to any (or many) of the bodies. You should still add only one of the objects to the Soft Body Collection (page 2–788).

Which parameters can I animate?

Only Wind (page 2–803) parameters are animatable.

Can a keyframed object participate in the simulation?

Yes. For objects that don’t change shape, and for which reactor should not create keyframes, use unyielding rigid bodies. For objects that change...
shape (deform), use deforming meshes (page 2–793).

Note: Unyielding rigid bodies are much faster and simpler to simulate than deforming meshes.

Can reactor store collisions for deformable bodies (Soft, Cloth, Rope)?

No. The storing collisions (page 2–774) functionality applies only to rigid bodies.

What are the limitations of Water (page 2–801) in reactor?

Water in reactor is simulated as a height field (points are displaced vertically only). This can produce effects like ripples and waves, but it cannot reproduce certain other effects:

- Wakes
- Splashes. You can, though, use the information exposed through MAXScript to generate particles or other effects.
- Flowing fluids (like water flowing through a pipe or pouring from a tap).

Can I move the center of mass of my objects? How?

You can’t explicitly set the center of mass of an object. However, you can use compound rigid bodies where different pieces have different masses to simulate uneven mass distribution. For example, you can simulate an object with a low center of gravity by dividing the object into two pieces (primitives), top and bottom, where the bottom piece is heavy and the top piece is light; alternatively, you leave the original piece intact, with low mass, and add a small, heavy primitive at the point of the desired center of mass. For more information, see Compound Rigid Bodies (page 2–722).

Can I attach Cloth/Rope/Soft Bodies to other Cloth/Rope/Soft Bodies?

No. However, once a piece of, say, cloth has been simulated, you can take it out of its Cloth Collection and add it to a Deforming Mesh Collection (page 2–794). By doing so, the cloth will still be part of the simulation the next time, but reactor won’t recalculate its animation. You can then attach other pieces of Cloth/Soft/Rope to it by using the Attach To Deforming Mesh (page 2–799) constraint.

How can I make a rigid body not move until a collision happens?

You can use the Inactive property for the rigid body.

How can I animate a floating object, like a balloon?

There are many alternatives you can try:

- Use water (page 2–801). The buoyancy of a balloon in the air follows the same rules as the buoyancy of a light object inside a fluid. You will need to place the water surface well above the scene so the objects are not visible when they reach it.
- Use very low mass for the objects, and add wind (page 2–803) blowing in the up direction.
Troubleshooting

You might want to also decrease the strength of gravity.

Check also: Frequently Asked Questions (page 2–821)

General Troubleshooting

Analyzing the World

Whenever you get unexpected behavior from reactor, it is advisable to perform a world analysis to get a report of anything detected by reactor as suspicious, unexpected, or prone to error in your scene. For more information, see reactor Utilities (page 2–813).

Discussion Forums

The Autodesk Web Forums provide you with a moderated community to discuss, learn, and share techniques and ideas with other 3D professionals. Need to know how to do something? Having a problem? Just want to show off your work? Post your questions to the appropriate forums.

Simulation takes too long.

General tip:

• Before performing a CPU-intensive operation such as Create Animation or Reduce Keys, make sure you don’t have any object selected in the scene. Having an object selected during some calculations can force 3ds Max to evaluate the selected object many times in order to update its UI, slowing down the calculations.

If the scene is complex but contains independent parts that don’t interact with each other, try adding the objects involved to different collections and solvers and create the animations independently for each subset, enabling and disabling the collections and solvers accordingly.

If you are using Soft Bodies, Cloth, or Rope (page 2–777):

• Try to reduce the complexity of the mesh that flows to the reactor modifier. For example, you can apply a MeshSmooth modifier on top of the reactor modifier to render a smooth surface while simulating a simpler one.

• For soft bodies with complex meshes, using FFD soft bodies (page 2–786) can offer better results and decrease the computation time.

• Unless necessary, do not use the Avoid Self-Intersections option, because it increases computation time and memory usage significantly.

• Try to reduce the number of substeps (page 2–806) used in the simulation. Also try to decrease the number of Internal Steps used by the Cloth/Soft/Rope collection.

Note: These steps also reduce the accuracy of the simulation, and can therefore cause instability.

If you are using rigid bodies (page 2–716):

• For best results when using rigid bodies only, set Utilities panel > reactor > About rollout > Choose Solver to Havok 3.
- Reduce the complexity of the geometry used for the rigid bodies. Try using bounding boxes or sphere, and avoid using non-fixed concave objects. Use simpler geometry as a geometry proxy (page 2–719) for the object.

- If you are using Fracture, slowdowns can be caused by reactor trying to avoid instability. Follow some of these tips (page 2–773) to help reduce the chances of instability happening.

- Try decreasing the number of substeps (page 2–806) used in the simulation. Be aware that this will reduce the accuracy of the solution and therefore may cause instability.

**Water doesn’t render.**

The reactor Water (page 2–801) is a world-space modifier and therefore it is not a renderable object. You can bind renderable object (like planes) to the water WSM in order to render a water animation. See Rendering Water (page 2–803).

**Cloth/Soft/Rope becomes unstable and explodes.**

- Check whether any unyielding rigid body or DefMesh (page 2–793) is forcing the Cloth/Soft/Rope into a penetration.

- If you are attaching to a rigid body (page 2–798), make sure that the points of attachment are outside the rigid body; otherwise, make sure Ignore Collision is on.

- If your Cloth/Soft/Rope is attached to a rigid body (page 2–798), use Runge-Kutta as the ODE Solver for the Rigid Body Collection (page 2–723) of the attached rigid body.

- Try increasing the amount of internal steps in the Cloth/Soft/Rope collection (Advanced rollout).

**Rigid bodies become unstable/explose/fly to infinity.**

In rare situations, simulation can become unstable and objects can “explode.” This typically happens only when using complex systems of objects, like Fracture (page 2–770), or using simple constraints (page 2–727) like springs or dashpots.

- For best results when using rigid bodies only, set Utilities panel > reactor > About rollout > Choose Solver to Havok 3.

- If you are using many simple constraints (page 2–727) (spring, dashpots) working together, switching the ODE Solver in the Rigid Body Collection (page 2–723) to Runge-Kutta can improve the results.

- Usually, increasing the number of substeps (page 2–806) in the simulation improves the stability of the simulation.

- Also for springs and dashpots, avoid attaching objects with very different masses. Using a Strength value similar to the mass of the objects attached, and a Damping value of 1/10th of that Strength usually give good results.

- If you are using constraints (page 2–724), make sure you have aligned the constraint spaces (page 2–725) properly.

- If many objects start the simulation too close to each other (inside collision tolerance), reactor will try to push them apart at the beginning of the simulation. Try increasing the space between them, or reducing the collision tolerance.

- If you have constrained two rigid bodies so they are in continuous contact/penetration (like an upper arm and a forearm), be sure to disable collisions (page 2–810) between those bodies.

- Adding drag action can help damp the overall simulation. Try increasing the linear drag in the scene.
If you are working with Fracture, the Fracture Tips (page 2–773) section provides information on how to avoid instability.

**Cloth/Soft/Rope object stretches too much**

If you have attached (using the Attach to RB Constraint (page 2–798)) it to a falling object, be sure to turn off Do Not Affect Rigid Body. If the problem remains, increase the mass of the Cloth/Soft/Rope, or decrease the mass of the attached rigid body. Increasing the strength and damping of the Cloth/Soft/Rope should also improve the situation.

**Objects seem to move very slowly**

Make sure you are using the proper World Scale (page 2–808) in the scene. A 10cm box falling from a 1m height doesn’t behave the same as a 1km box falling from a height of 10km: The second one will reach the ground much later). Use real-world units or have a proper mapping between 3ds Max units and simulation units (World Scale (page 2–808)).

**Why, after simulation, do I get warnings regarding "topology changes"?**

The term “topology” refers to the internal connections of the vertices, edges and faces of a mesh. If you change the number of vertices in a mesh, you are changing its topology. While 3ds Max lets you animate the topology of objects (e.g., change the number of vertices or faces over time), reactor can simulate only objects with fixed numbers of vertices. If, during a simulation, reactor detects a topology change, it ignores the object in question and reports the problem as a warning.

**Objects interpenetrate.**

There can be different reasons for this:

- Check that you haven’t disabled collisions for those bodies. You can disable collisions either globally (page 2–810) for pairs of objects, or for the object in particular (Rigid Body Properties (page 2–717)).
- If the objects are attached using deformable constraints (page 2–795), make sure you haven’t disabled collisions in the constraint parameters.
- Make sure Collision Tolerance is set to a value that makes sense for the sizes of the objects.
- Try increasing the number of substeps (page 2–806) in the simulation.

**Cloth/Soft/Rope intersects itself.**

Make sure you have turned on the Avoid Self-Intersections option in the modifier (page 2–777).

**I can’t add an object to a Cloth/Soft/Rope Collection.**

Only an object that has the proper reactor modifier applied can be added to one of these collections. Make sure you have applied a reactor Cloth (page 2–778), Soft Body (page 2–784), or Rope (page 2–789) modifier to the object.

**I can’t add an object to a Rigid Body Collection.**

If you are using compound bodies (page 2–722), make sure the group is open, as only the group parent can be added to a Rigid Body Collection (page 2–723).

**Mass and other properties are disabled.**

Make sure you have selected only one object, and that this object is geometrical. The most common cause for this is the use of groups. You can use groups to create compound rigid bodies (page 2–722), but in order to change the properties of
the primitives inside the group, you'll need to open it and selected the individual primitives inside it.

**Rigid bodies don’t bounce enough.**
Increase the Elasticity property (page 2–717) of the object. Try also increasing the Elasticity of the other object involved in the collisions, as the elasticity of a collisions is a function of the elasticity property (page 2–717) of the two objects involved.

**Objects stop moving unexpectedly in the middle of a simulation.**
This can be caused by objects being deactivated. There are two ways objects can be deactivated: through the world (page 2–808) deactivation or, if the object belongs to a constrained system, through the Constraint Solver (page 2–736) deactivation parameters
In both cases, try modifying the deactivation parameters for a less-aggressive deactivation, or disable deactivation in general.

**An object doesn’t move during the simulation.**
Make sure that you've added the object to a RBCollection (page 2–723) and that it has a mass (page 2–717) other than 0.0 (objects with mass 0.0 are fixed). If you are using Fracture (page 2–770), make sure none of the pieces is fixed (has mass 0.0).

**A keyframed object doesn’t move during the simulation.**
Make sure that you enabled the unyielding (page 2–717) property for that rigid body.

**My old scripts don’t work.**
reactor exposes parameters and functionality to MAXScript in a much more consistent and complete way than previously. For the update, some reactor MAXScript interfaces had to be renamed, but all functionality exposed in previous versions is still available, and a lot more functionality has been exposed. While this means that some reactor-specific scripts need to be updated, it also means that a great deal more flexibility and power is now achievable using MAXScript with reactor. For more information, see the MAXScript Reference, available from the Help menu.

**I can’t I disable collisions between two bodies.**
If your objects don’t appear in the Define Collisions dialog (page 2–811), make sure you’ve added the two bodies to a collection; only objects in collections are shown in that dialog.

**Rigid bodies don’t sink/don’t float in the water.**
Objects sink or float depending on their density and the density of the water. You define water density explicitly in the Water space warp (page 2–801). The density of a rigid body is defined as its mass divided by its volume.

- Check that your objects have real-world sizes (or adjust the world scale (page 2–808)) and masses (page 2–717).

If your bodies still don’t sink enough for your liking, try the following:
- Increase the mass of the bodies.
- Decrease the density of the water.
- Decrease the viscosity of the water, this can slow down the sinking.

Follow the opposite steps if you’re trying to make your objects float more.

**Water doesn’t ripple enough**
You can either increase the Max Ripple value in the Water space warp (page 2–801), or you can scale the effect of the space warp on a particular object.
that you’ve bound to the space warp by modifying the Scale Strength value in the Water world-space modifier (page 2–803). The first option (increasing the Max Ripple value) is preferable, but you need to re-create the animation in order to see the effect. The second option (increase the Scale Strength parameter in the modifier) affects only the object bound to the Water space warp. It can thus produce inconsistent results if you have objects floating in the water, because they won’t be affected by the change.

I can’t see any stored collisions.

Make sure you’ve set reactor to store collisions (page 2–774) during the simulation. Collisions are stored only for rigid bodies; not for Cloth, Soft Bodies, or Rope.

Constrained objects snap at the beginning of the simulation.

During a simulation, reactor tries to match the two constraint spaces (sub-objects) defined in the constraint (see Constraint Concepts (page 2–725) for more info). When you create a constraint those spaces are aligned by default. After setup, each space moves with the corresponding attached object. If you have moved the objects and wish to realign the constraint spaces, there are tools in the helper to do so (see Working With Constraint Spaces (page 2–726) for more info).

File size increases dramatically.

- If you are using rigid bodies, try the Reduce Keys (page 2–813) utility to reduce the number of keyframes created for each rigid body.
- FFD-based soft bodies (page 2–786) can also create a large number of keys in the FFD modifier (one for each vertex for each frame). Although the Reduce Keys (page 2–813) functionality in reactor applies only to rigid bodies, you can reduce keys in the FFD modifier using the 3ds Max Reduce Keys tool, available from Track View (page 2–501).

reactor runs out of memory during simulation.

Reduce the complexity of the objects simulated:

- For rigid bodies, use a simpler geometry or proxy (page 2–719) to simulate the object.
- For Cloth and Soft Bodies, try to use a coarse mesh for the simulation, then apply a MeshSmooth modifier on top of the reactor modifier to smooth the final result.
- For Soft Bodies, try to use FFD-based Soft Bodies (page 2–786) instead of mesh-based soft bodies.

For any deformable body, the Avoid Self-Intersection option is particularly memory-intensive. Avoid using this option if you are having problems regarding memory.

Using FFD-Based Soft Bodies to animate a part of a mesh, the whole object seems to be rotated by the simulation.

If you are using FFD Soft Bodies (page 2–786) to animate just a subpart of a mesh, make sure the Animate Transform check box is off, as this option works only for FFD animating the whole mesh.

Using FFD-Based Soft Bodies to animate a whole mesh, some weird squashing happens on occasion.

If you are using FFD Soft Bodies (page 2–786) to animate the whole mesh, sometimes the FFD modifier deformation can show artifacts when the lattice points are rotated. Try switching on the Animate Transform check box in the modifier to avoid those artifacts.
Picking objects during preview makes them go unstable.
Try reducing the strength and damping of the mouse spring on the Display rollout (page 2–812).

Objects barely move when picking during preview.
Try increasing the strength and damping of the mouse spring on the Display rollout (page 2–812).

I can’t see anything in the Preview Window.
It might be caused by the lack of a proper camera; create a camera and select it in the Display rollout (page 2–812). If still doesn’t work, try changing the far and near clipping planes.

The preview shows everything in black.
If the scene uses texture maps but the software can’t find the map files, they’re shown as black. Disable textures by pressing [X] during the preview (page 2–815).

After the simulation I get a warning reporting that objects moved to infinity.
When instability occurs, rigid bodies can reach extreme velocities and therefore move to infinity. If reactor detects this condition when creating an animation, it does not create keyframes, but instead reports the problem once the animation is finished.
Check also the Rigid bodies become unstable (page 2–824) section above.

There is a visible gap between rigid bodies in the simulation.
Try reducing the Collision Tolerance of the simulation.

reactor complains about a no longer existing node.
This can happen if you rename an object that is used as geometry or display proxy (page 2–719) for a rigid body; proxies are stored by name, so if you change the name of the proxy you’ll have to manually update the rigid bodies that use it.

Error : All vertices are coplanar, use concave mesh.
By default, geometries in reactor are simulated using their convex hull. reactor can’t create a convex hull from geometry in which all the vertices lie in the same plane, such as a standard 3ds Max plane. Those geometries need to be simulated as concave. Check the Rigid Body Properties (page 2–717) section for more information.

Rope simulation modifies the smoothness of the spline.
Although reactor simulates cloth as a series of linked vertices, the Rope modifier (page 2–789) tries to produce a smooth curve going through the vertices. In most cases the curve generated by the modifier is suitable, but in some cases (for example, if the vertices in the spline are far apart) you might find that the generated curve is not optimal. In those cases you can:
• Modify (refine) the spline below the Rope modifier so there is a uniform distance, not too great, between vertices. You will need to re-create the animation in order to see the final results.
• Modify the spline after the Rope modifier using an Edit Spline modifier (page 1–680). This is the most flexible option.

Animation works in the preview, but not in 3ds Max after creating the animation.
reactor creates the animation for rigid bodies (page 2–716) by sending transforms (new rotation
and new position) to the controllers assigned to those bodies. Some controllers, like procedural controllers (Noise) and some system controllers (Biped) do not handle these explicit transform updates. To overcome this, assign a regular keyframable controller such as Euler XYZ or Bezier to the objects or, if that’s not possible or desirable, create a copy or snapshot of the bodies and make sure that a suitable controller is assigned to the snapshot copies. Use these copies for the reactor simulation instead.

**Rigid bodies in animation flicker and jump when playing the animation but not when moving the time slider.**

This is usually a problem with the subframe interpolation of the Euler (XYZ) rotation controller. While reactor sends valid transformation keys to the controller, the conversion from an arbitrary rotation to X, Y and Z Euler angles may cause non-smooth animations between keyframes (the controller produces noncontinuous X, Y and Z values). This problem can be solved by using a quaternion-based rotation controller, such as the TCB controller, for the rigid bodies.

**Preview Animation fails**

While the *Preview Window* should work with most OpenGL and DirectX compliant hardware, some specific hardware and driver configurations might cause problems:

- Update to the latest drivers for your graphics card. Refer to the manufacturer’s Web site for details.
- Try to use DirectX instead of OpenGL (or vice versa) for the preview. This setting, independent of what is used for the 3ds Max viewports, can be changed on the *Display rollout*. If you discover that your card works only with a particular configuration, you may want to create startup script (a script in the *scripts/startup* folder) that calls `reactor.displayUsingDirectX = true/false`.
- Some problems can be caused by lack of display memory. Avoid having multiple sessions of 3ds Max open at the same time, and reduce the size of the windows and the display resolution.
- Try changing the 3ds Max to different drivers: OpenGL, Direct3D or Software.

**Wind doesn’t seem to work**

- Make sure the Wind Helper icon is pointing towards the right direction.
- If the wind should act upon cloth, rigid bodies, etc., make sure the correct check box is on in the Wind Helper parameters.
- Try to increase the strength of the wind, or decrease the weight of the objects it should affect.
The **character studio** functionality in 3ds Max provides professional tools for animating 3D characters. It is an environment in which you can quickly and easily build skeletons and then animate them, thus creating motion sequences. You use the animated skeletons to drive the movement of geometry, thus creating virtual characters. And you can generate crowds of these characters using **character studio**, and animate crowd movement using a system of delegates and procedural behaviors.

**character studio** comprises three components: Biped, Physique, and Crowd.

- **Biped (page 3–916)** builds and animates skeletal armatures, ready for character animation. You can combine different animations into sequential or overlapping motion scripts, or layer them together. You can also use Biped to edit motion capture files.

  *Note:* Biped does not create character mesh objects. You should create your character mesh before using Biped to create a skeleton for it.

- **Physique (page 3–994)** uses the biped armatures to animate the actual character mesh, simulating how the mesh flexes and bulges with the movement of the underlying skeleton.

  *Note:* You can use Physique with other hierarchies beside the biped skeleton.

- **Crowd (page 3–925)** animates groups of 3D objects and characters using a system of delegates and behaviors. You can create crowds with highly complex behaviors.

If you are new to 3ds Max, read What You Should Know to Use character studio (page 2–832) and Understanding character studio Workflow (page 2–839).

If you are already a 3ds Max user, proceed to Understanding Biped (page 2–833) to continue.

To find out about Physique, read Understanding Physique (page 2–834).

To learn about the Crowd system, read Crowd Animation (page 2–1154).

---

**What is character studio?**

**character studio** is a set of components that provides a full set of tools for animating characters.

**character studio** lets you create skeletal hierarchies for two-legged characters (called *bipeds*) that can be animated quickly using a wide variety of methods. If your character walks on two legs, the software provides unique **footstep animation** (page 2–856) that automatically creates movement based on gravity, balance, and other factors.
If you want to animate motions manually, you can use freeform animation (page 2–886). This type of animation is also suitable for characters with more than two legs, or characters that fly or swim. With freeform animation, you can animate the skeleton with traditional inverse kinematic techniques.

You can also animate a biped skeleton by loading motion capture files (page 2–925). You can convert back and forth between these methods to take advantage of their several benefits.

character studio also provides tools for skinning a character using the biped skeleton, or any other type of linked hierarchy.

The software provides a unique ability to separate the motion of the animation from the structure of the character. This means you can animate a giant walking and apply that motion to a tiny elf, or animate a fat character and retarget the same motion to thin one. Using a library of motions, you can animate a character doing hundreds of different actions, as easily as loading a file.

The software provides a comprehensive range of tools for motion editing. You use motion scripting to sequence animations with transitions. Different animations can be overlaid using layers, or blended with the new nonlinear Motion Mixer (page 2–604).

You can use function curve editing, available on the track bar or in Track View, or in the new Animation Workbench (page 2–1008), to alter animations. The workbench also provides specialized tools to analyze and correct errors in motion. Finally, the software provides options for creating crowds of bipeds (page 2–1154) or other objects with a procedural animation system that uses forces and behaviors to drive the characters’ motions.

character studio consists of three basic components:

- **Biped** provides tools to create and animate skeletons.
- **The Physique** modifier (page 2–1076) associates a skeleton with the character’s mesh objects, so you can control the mesh with the skeleton.
- **Crowd** provides tools to create and animate crowds of animated objects, including bipeds.

---

**What You Should Know to Use character studio**

character studio provides you with a broad range of tools for animating virtually any type of character. To expedite your introduction to the product, you should be familiar with the following 3ds Max concepts:

- Creation, transformation, and modification of objects
- Selection of objects through clicking or dragging in viewports, and by using the Select Objects dialog (page 1–78)
- Navigation in viewports and changing your viewport configuration
- Use of the Track View - Dope Sheet and Track View - Curve Editor, and the trackbar to view and edit animation tracks and keys
For information on these areas, consult the remainder of this reference. If you don’t know how to use 3ds Max, do some of the introductory tutorials found online in Help > Tutorials.

Understanding Biped

*Biped (page 2–843)* is a 3ds Max component that you access from the Create panel. Once you create a biped, you animate it using the Biped controls on the Motion panel. Biped provides the tools you need to design and animate the figures and motion of characters.

The Biped

The biped skeleton created with the Biped module is a two-legged figure created as a linked hierarchy, and designed for animation. The biped skeleton has special properties that make it instantly ready to animate.

Figure and Keyframe Modes

*character studio* is designed to interchange motion and characters. In *Figure mode (page 2–982)*, you pose the biped to fit your character model. In *Keyframe mode (page 3–960)*, you animate the skeleton. Motions created for the biped can be saved and loaded onto other biped skeletons with completely different physical characteristics. For example, you could animate a giant ogre, save the animation, and load it onto a small child. Motion files are saved in the proprietary *character studio BIP format (page 3–916)*.

These files can be used in a variety of ways with Motion Flow, the Motion Mixer, or the Crowd tools to combine animation or animate multiple characters at once.

 Animating the Biped

There are two primary methods used in creating biped animation: *footsteps method (page 3–943)* and *freeform method (page 3–945)*. Each method has advantages. You can convert from one method to the other, or you can use a combination of both techniques in a single animation. For detailed information, see the sections that follow: *Creating Footstep Animation (page 2–856)* and *Creating Freeform Animation (page 2–886)*.

Biped Properties

The biped skeleton has a number of properties designed to help you animate faster and more accurately.

- **A human structure**—Joints on the biped are hinged to follow human anatomy. By default, the biped resembles a human skeleton and has a stable inverse kinematics hierarchy. This means that when you move a hand or foot, the corresponding elbow or knee orients itself accordingly, and produces a natural human posture.

- **Customizable for non-human structures**—The biped skeleton can easily be made to work with a four-legged creature or an animal that naturally leans forward, such as a dinosaur.

- **Natural rotations**—When you rotate the biped spine, the arms maintain their relative angle to the ground, rather than behaving as if they were fused to the shoulders. For example, say the biped is in a standing position, arms hanging at its sides; when you rotate the spine forward, the biped’s fingers will touch the ground rather than point behind it. This is a more natural position for the hands, and this speeds the process of keyframing the biped. This feature also applies to the biped head. When you rotate the spine forward, the head maintains a forward-looking orientation.
• **Designed for footsteps**—The biped skeleton is specially designed to animate with **character studio** footsteps, which help solve the common animation problem of locking the feet to the ground. Footstep animation also provides an easy way to rough out animation quickly. See the section *Creating Footstep Animation (page 2–856)*.

### Understanding Physique

Physique is a modifier that, when applied to a mesh, allows the movements of an underlying skeleton to move the mesh seamlessly, like bones and muscle under a human skin. Physique works on any point-based objects including geometric primitives, editable meshes, patch-based objects, NURBS, and even FFD space warps. For NURBS and FFDs, Physique deforms the control points, which in turn deform the model. It will attach to any skeleton structure including a biped, 3ds Max bones, splines, or any 3ds Max hierarchy. When you apply Physique to the skin object(s) and attach the skin to the skeleton, Physique determines how each component of the skeleton influences each vertex of the skin, based on settings you specify.

Physique affects a mesh after you click Attach To Node on the Physique rollout and select a root node in the viewports. During the attach process, Physique works its way through all of the children in a hierarchy, starting at the object you select, and creates its own links with associated envelopes (page 2–1085) for each link it finds. The links created by Physique are referred to within this documentation as the Physique deformation spline (page 3–927). Vertices that fall within envelopes are influenced to follow the links and animate the mesh. Splines and 3ds Max bones can also be added using the Add button in the Floating Bones rollout (page 2–1110).

### Biped and Physique

When the biped pelvis is selected in the viewports and **Attach To Node (page 2–1106)** is turned on, Physique traces its way from the pelvis down the legs to the toes. From the pelvis it also traces its way up through the spine and branches at the collar to the arms, hands, and fingers, and up the neck to the head. A link and associated envelopes are created for each link found. If any other objects, including 3ds Max bones, are linked to the biped, Physique treats them similarly: it creates a new link and envelopes.

Keep this in mind when you use Physique to attach a mesh to the biped; if your character has additional limbs, link 3ds Max bones to the biped for the extra arms before using **Attach To Node** to create links and envelopes. When Physique is applied and Attach To Node is used, it creates links and envelopes for all the links in the biped, as well as for the linked bones. Objects that should not deform, like skin, but need to be linked to the biped, like a sword, should be linked after **Attach To Node** is used to link a mesh to the biped. This way, a link and envelopes will not be created for the sword.
Envelopes and Weighted Vertices

Envelopes are the Physique modifier’s primary tool for controlling skin deformation; tendons and bulge angles are used to fine tune mesh deformation after envelopes are adjusted. All envelopes have an inner and outer bound (boundary). Vertices falling within the inner bound of a single link receive a full weight of 1.0 from that link. Those falling outside the outer bound receive no weight from that link. Vertices falling between the inner and outer bounds receive a weight between 0 and 1.

Vertices move together with the link that influences them. Where multiple envelopes encompass a vertex, that vertex receives weight from each envelope and follows each link to an average position based on these weights. This weighting from multiple links is considered blending. It is possible that weights assigned to some vertices don’t reach a total weight of 1.0 or greater. Rather than leaving these vertices behind, Physique by default normalizes them to a value of 1.0.

Adjusting falloff, overlap, scale, and other envelope parameters changes vertex weight distribution across links. This, in turn, changes the way skin behaves as the biped moves. Much of the work you’ll do to correct the way skin deforms on a character will be to adjust envelopes.

Deformable and Rigid Envelopes

There are two Envelope types per link, deformable (page 3–927) and rigid (page 2–1085). Deformable envelopes follow the Physique deformation spline that runs through the joints in the hierarchy, and can be deformed using bulge angles, tendons, and link parameters. Rigid envelopes determine vertex-link assignment based upon the linear 3ds Max link and move in an immobile relationship to the link. Vertices in a rigid envelope, however, are deformed (blended) in the overlap area of other envelopes.

Typically you use deformable envelopes; however, game developers with game-engine restrictions may want to use rigid envelopes exclusively. Both rigid and deformable envelopes can be turned on for the same link. For example, by scaling both envelopes, you could deform the shoulder with a rigid envelope and the armpit with a deformable envelope.

The Number of Links That Can Affect a Vertex

Any number of overlapping envelopes ($N_{\text{Links}}$ (page 3–978)) can influence vertices. Normally, $N_{\text{Links}}$ are preferred. For special purposes such as games requirements, you can limit the number of links (envelopes) that can affect a vertex. The No Blending parameter is similar to the method used in version 1 of the software; a vertex is assigned to only one link.

Physique Workflow

Before Physique is applied, align the biped to the mesh in Figure mode (page 2–982). Use a pose with the arms outstretched so the hands are away from the torso. Save a figure file, so it’s easy to return to this pose whenever you need. Select the mesh and choose Physique in the Modify panel. Turn on Attach to Node and select the root node in the hierarchy (biped Pelvis or root node in a bones hierarchy, not the COM). In the Physique Initialization dialog, click Initialize to create default envelopes based on the links in the hierarchy. The remainder of the work is adjusting envelopes and optionally adding bulge angles and tendons.

Envelope size, overlap, and other parameters are adjusted with the character in an animated position (with Figure mode turned off). By scrubbing the time slider back and forth, you can spot problem areas and adjust the envelopes affecting the problem areas. In Place mode is
useful to keep the character stationary during envelope adjustment.

Link parameters, Bulge angles and tendons are the finishing touches. Skin sliding, the amount of twist, and crease blending as a character moves are controlled using link parameters. Bulge angles are used to bulge areas like the biceps, legs and chest relative to the angle created by a link and its child in the hierarchy. Tendons can span multiple links in the hierarchy to stretch and pull a character’s skin.

Understanding Track Editing
There are several places to view your animation represented as tracks in 3ds Max. These views include:

- Track View - Curve Editor
- Track View - Dope Sheet
- Track Bar

The tracks can be displayed as function curves, or as keys and ranges on a box graph. character studio makes special use of function curve editing capabilities with a customized version of the Track View - Curve Editor called the Animation Workbench (page 2–837).

Biped Curve Editing Using the Track Bar
After creating animation of the biped in the viewport using keyframing tools from the Motion panel, you might need to work on the animation tracks, either to adjust key interpolation for smooth motion or to adjust ranges and affect timing. 3ds Max allows for a number of basic ways to do these tasks for all scene objects using direct key manipulation.

The simplest and most direct access to keys and ranges can be found on the track bar. Keys for selected biped objects are immediately visible there. With some limitations, you can create keys by [Shift]-dragging in the track bar. Right-clicking any key will display a menu; choosing from this menu will give quick access to key properties such as interpolation controls. This Key Properties dialog is also accessible from a list on the Motion panel > Assign Controller rollout.

A right-click on the time slider also displays the Create Key dialog, which is another quick way to set keyframes.

Selecting any two keys displays the range as a bar beneath the keys. You can reposition this range bar or resize it to adjust the timing of the animation. You can combine accelerator keys, like [Ctrl] and [Alt] with left, middle, and right mouse buttons to extend or stretch the range displayed in the track bar.

You can expand the track bar to quickly display the keys on function curves. From there, you can select and manipulate keys.

Biped Curve Editing in Track View
The same function-curve editing controls are found in Track View. Track View has two modes: Curve Editor and Dope Sheet.

character studio displays function curves for biped components in the Track View - Curve Editor.

Dope Sheet mode displays the footstep tracks and other biped keys as boxes. Here, you cut, copy, and paste keys to create repeated motion. You can use Time Editing in Dope Sheet mode, and cut, copy, paste, and insert time segments, complete with keys, into your animation.
Curve display can help pinpoint troublesome spots in your animation. You can see where a curve has problems, usually corresponding to motion problems in the viewport animation. You move the keys to compensate for the problems.

**Understanding the Workbench**

The Workbench is a curve editor customized for use with character studio. It provides specialized tools for selecting and displaying curves, and also for locating and fixing errors and discontinuities in motion. It is a visualization tool that allows you to see and manipulate quaternion function curves represented as euler angles. Also you can see curves for the the position of a biped body part in any coordinate space.

The Workbench automatically limits selections to just biped body parts and scene objects related to that biped. You can analyze these for errors using a variety of detectors, and fix them using the provided fixers. You can also apply filters to perform operations on different biped body parts to generally affect the animation without error identification.

Function Curve editing for Biped is also available in the 3ds Max Track View - Curve Editor and in the expanded track bar, but without the specialized Workbench tools.
